FOREWORD

Owners of profitable poultry flocks owe much of their success to diligence in combating diseases. Poultry are subject to a wide variety of infections, some of which respond readily to treatment, whereas others resist control measures and cause discouraging losses.

A knowledge of the characteristics of each disease is necessary, therefore, as the first step in building up an effective barrier against it. Scientific research already has provided much information of this nature, highly useful as a guide throughout the poultry enterprise. Large expenditures of money, time, and labor are still being made by poorly informed, misguided poultrymen in attempting to control disease by futile means.

With the gradual unfolding of scientific knowledge concerning poultry diseases and parasites, the influence of various infections in connection with breeding, nutrition, housing, and management becomes more and more apparent. This volume contains discussions relating to these and allied phases of poultry raising. The authors, who are specialists in their respective fields, encourage a wider application of sound practices recommended for conquering diseases.

This unusually comprehensive book is intended for students, veterinarians, pathologists, and workers in specialized fields. Trained persons usually are best able to make proper diagnoses of disease conditions and to direct proper courses of treatment.

Finally, the suppression of poultry maladies has a public as well as private aspect. The effect of a loss caused by disease is seen and felt first by the flock owner, but the presence of a transmissible infection is a danger

to neighboring flocks as well. Moreover, large numbers of small individual losses add up to a substantial national total. I trust, therefore, that this book may have a far-reaching influence in improving poultry health, with benefits to the poultry industry and the national welfare.

PREFACE

During the six years that have elapsed since the publication of the fourth edition of Diseases of Poultry in 1959 many new developments have occurred in the system and methods of poultry production. At that time the elimination of many small producers and independent local hatcheries was noted. The trend has continued toward larger production units, and the application of more advanced genetic guidance.

The rapid advances made in the knowledge of poultry diseases by an ever-increasing number of highly trained researchers from various basic disciplines has created a tremendous amount of scientific literature. It is hoped that this volume encompasses much of this information for use by the industry, and that it will serve as a starting point for future research.

We also trust that the book will continue as in the past to be of service to public health workers as it concerns diseases transmissible to man, especially ornithosis, salmonella infections, and Newcastle disease.

The thoughts expressed in the foreword of the first edition, so well written by the late Dr. John R. Mohler in 1943, have not been altered by the passing of time.

Again the editors welcome the new contributors to the fifth edition. To these new authors and to past authors who made possible the undertaking during the last 35 years this book is dedicated.

At this time we express the highest tribute to the memory of Dr. Erwin L. Jungherr, one of the charter authors who was taken from our midst on April 16, 1965, only one month after he had returned the revised galleys of his chapters. Dr. Erwin L. Jungherr's sincerity, research competence, and integrity,

[xi]

and his tireless and patient efforts in cooperating with the editors established a lasting image of respect and friendship for this man.

Again, grateful acknowledgment is made to Director Robert W. Orr of the Iowa State University Library and to Elizabeth A. Windsor and Mrs. Mildred E. McHone of the Reference Department during the extensive bibliographic work in connection with the book.

The counsel and guidance of Mr. Raymond Fassel of the Iowa State University Press and others were most helpful.

Avian Anatomy

AFFINITIES OF REPTILES, BIRDS, AND MAMMALS

The birds like the mammals arose from the reptiles but from different ancestors. Both classes appeared during the Jurassic, the mammals from the reptilian Subclass Synapsida, Order Therapsida, and Suborder Theriodontia, and the birds from the Subclass Archosauria (a diapsid reptile), Order Thecondontia, and an ancestral line in or close to the Suborder Pseudosuchia. The ancestral birds lived contemporaneously with the dinosaurs and flying reptiles.

Birds and mammals have pursued their evolutionary development independently of each other and by no means can one class be considered either more primitive or more highly developed than the other; each has specialized in different directions. Reptilian cousins of the birds are represented today in *Sphenodon*, and in the crocodiles, lizards, and snakes, whereas all of the synapsid reptilian lines related to

mammals became extinct in the Jurassic. In part mammals seem farther removed from their reptilian progenitors than do the birds because there are no living descenders of the theriodonts. The birds share many structural features with their living reptilian cousins and any real understanding of avian anatomy is dependent upon at least some familiarity with the structure of reptiles.

FIG. 1.1 — A section of skin from the femoral tract of a 20-day-old chicken embryo. a., artery; conn., connective; m., muscle; tiss., tissue. (From USDA.)

INTEGUMENTARY SYSTEM

Histology of the Skin

The skin is composed of two principal layers, *epidermis* and *dermis* (Fig. 1.1), the first derived from the embryonic ectoderm and the second from the mesoderm. The epidermis of birds is thin except in naked or modified areas and is composed of relatively few layers of cells compared to mammals. The dermis also is thin in non-feathered areas protected by overlying plumage; it is considerably thicker in those parts that carry the implantation of feathers. The skin is usually dense and tough in highly vascularized, exposed areas such as ear lobes, comb, and wattles of the chicken and on the nearly naked head and neck of the turkey. Intense keratinization of the epidermis may produce tough, specialized structures such as spurs, claws, scales, and beak.

The epidermis in most parts of the body is composed of but two layers, the *stratum germinativum* and the *stratum corneum*. The basal cells of the germinative layer are larger than those more superficially placed, which are transitional toward the flat-

tened, keratinized, dead cells of the corneal layer. In the epidermis covering the claws, the transition layer may properly be called a *stratum spinosum*; in this location a *stratum granulosum* is also present but in most parts of the body, the transition to the corneum is a gradual one. A *stratum lucidum* and a basement membrane are absent in birds.

The dermis is so variable in thickness and complexity of tissue structure that it does not readily lend itself to a generalized subdivision into layers. In a feathered area (Fig. 1.1) the dermis is slightly more dense and cellular in the area beneath the epithelium than in its deeper parts. Dermal papillae, typical of mammalian skin, are absent in birds except in the feet.

The feather follicles project into the dermis and the smooth muscles that move them are located in this layer. The collagenic connective tissue bundles of the superficial layer intertwine in all directions and usually the layer is well vascularized. Corpuscular types of nerve endings are abundant, particularly Vater-Pacini and Grandry. The dermis in the apteria of the body contains near its lower surface a flat

thin layer of smooth muscle bundles, the ends of which are united by dense bands of elastic tissue, organized in such a way as to form a network structurally capable of moving the nonfeathered skin.

Elastic fibers are scattered among the collagenic fibers and in addition usually form a thin but definite layer near the lower surface of the dermis in a network parallel to the surface of the skin. Elastic tissue forms the tendons that connect the feather muscles to the follicles.

The subcutis may be areolar or adipose tissue. Liebelt and Eastlick (1954) have given names to 16 subcutaneous fat bodies and have illustrated their positions and shapes in the late chick embryo. Much of our basic information on the histology of the avian skin comes from the publications of Moser (1906), Greschik (1916), and Lange (1928, 1931).

Feather Tracts and Spaces

Contour feathers are arranged in rows within tracts (*pterylae*) in the skin of most birds. The tracts are separated by nonfeathered spaces (*apteria*). The arrangement of feathers was first described by Nitzsch (1867) and has been the subject of numerous studies such as those by Pycraft (1898), Steiner (1917), Boulton (1927), Compton (1938), and Humphrey and Clark (1961). The embryonic development of *pterylae* has been investigated by Holmes (1935), Gerber (1939), Wetherbee (1957), and Komarek (1958).

The more important *pterylae* and *apteria* are listed below and those visible in a lateral view of a chicken are shown in Fig. 1.2.

Pterylae

1. Capital tract—head. This tract has numerous subdivisions.
2. Dorsal cervical tract—dorsal surface of the neck.
3. Ventral cervical tract—ventrolateral surface of the neck.
4. Interscapular tract—dorsal mid-region between the shoulders.
5. Dorsal and pelvic tracts—dorsal surface of the trunk.
6. Pectoral tract—ventrolateral surface of the breast.
7. Lateral body tract—side of body near axillary fossa.
8. Sternal tract—ventral side of trunk on each side of the keel.
9. Abdominal tract—ventral side of the abdomen.
10. Humeral tract—dorsal surface of upper arm near shoulder.
11. Alar tract—dorsal and ventral surfaces of the wing. This tract has numerous subdivisions.
12. Femoral tract—thigh region.
13. Crural tract—leg region.

Apteria

1. Lateral cervical apterium—side of the neck, between dorsal and ventral cervical tracts.
2. Ventral cervical apterium—ventral surface of neck, between right and left ventral cervical tracts.
3. Scapular apterium—between interscapular and humeral tracts.
4. Lateral pelvic apterium—between pelvic and femoral tracts.
5. Lateral body apterium—space surrounding the lateral body tract.
6. Pectoral apterium—between pectoral and sternal tracts.
7. Sternal apterium—over the keel, between right and left sternal tracts.
8. Crural apterium—knee region, between crural and femoral tracts.

Feather Types

Feathers vary in complexity from a simple down feather that is entirely plumulaceous (fluffy) to the intricate contour feather that is partly pennaceous (closely knit texture) (Fig. 1.3). A semiplume is an intermediate type of feather, characterized by plumulaceous structure but having a distinct rhachis. The rhachis is that part of the shaft that bears filaments (barbs). In the contour feather the barbs project from the two sides at about a 45° angle and in turn lesser filaments, the barbules, project distally and proximally from the margins of each barb at about a 45° angle. The result is that the barbules cross each other at about a 90° angle: one set of barbules carries hooklets that loosely engage the flanges of the barbules that cross beneath them. It is this mechanism that gives stiffness and cohesiveness to the vanes of contour feathers. At the base of the feather, the hooklets and often the barbules themselves are absent and because the barbs are unrestrained they produce a fluff or plumulaceous portion of a feather.

planted end of the shaft) a miniature feather (afterfeather, s. aftershaft) emerges from the inferior surface and parallels the rhachis. This structure is present in chickens and turkeys, rudimentary in ducks, and absent in pigeons (Miller, 1924). Afterfeathers are absent from natal down of all species.

The largest contour feathers are the flight quills on the wings and tail: the remiges and rectrices respectively. There are 10 primary remiges implanted on bones of the hand of most birds. On the wrist there is a vestigial feather, the carpal remex, that is frequently overlooked. The ulna of the forearm carries 16–19 secondary remiges in chickens, the first of which is shorter than the feathers adjacent to it and is often called the axial or key feather. There are 6–8 pairs of rectrices in the chicken; the median pair of which, in the

male, forms the greater sickles. Smaller feathers, the coverts, overlie the bases of remiges and rectrices.

Contour feathers are modified in various ways; the outer margin of the hackle feathers of the cock is devoid of barbules. The barbs of auricular feathers are stiff and far apart which provide an effective screen but do not interfere with the passage of sound. Bristle feathers consist of a shaft that is either entirely bare or has a few barbs at the base. They are found on the carunculate skin of the head and neck of turkeys and at the corners of the mouth in various other birds. Bristles on the eyelids are known as eyelashes or, if tiny, as cilia.

Down feathers form the first plumage of birds; they are also present later at the margins of the tracts in chickens and pigeons, and among the contour feathers

Contour feathers are modified in various ways: the outer margin of the hackle feathers of the cock is devoid of barbules. The barbs of auricular feathers are stiff and far apart which provide an effective screen but do not interfere with the passage of sound. Bristle feathers consist of a shaft that is either entirely bare or has a few barbs at the base. They are found on the carunculate skin of the head and neck of turkeys and at the corners of the mouth in various other birds. Bristles on the eyelids are known as eyelashes or, if tiny, as cilia.

Down feathers form the first plumage of birds; they are also present later on margins of the tracts in chickens and pigeons, and among the contour feathers
in ducks. Their long, flexible barbs usually arise from a very short rhachis. In the natal downs of certain birds, the barbs arise from the upper end of the calamus. The barbs bear barbules composed of a series of simple segments without hooklets.

After a chicken has been plucked there remain numerous hairlike feathers called filoplumes. Typically they have a calamus and a slender, long rhachis with a tuft of barbs at the tip. They bear no afterfeathers in any species of bird. Their function is unknown. In the chicken they are longest on the neck and back and are most numerous around the remiges.

Feather Musculature

The contour feathers of the body can be readily elevated or depressed, as seen in the hackles of the crowing cock and also seen in the body feathers when bathing or dusting. These actions are controlled by a network of smooth muscles innervated through the sympathetic nervous system (Langley, 1904; Ostmann et al., 1963). To the unaided eye the bundles of smooth muscles join all adjacent follicles and in the network have the arrangement of parallelograms. In some fiber-tracts, muscle bundles cross diagonally joining opposite corners.

A dissection of the feather musculature under the microscope makes it evident that the bundles of muscles are arranged as antagonists, erectors, and depressors (Stettenheim et al., 1963). One end of a muscle unit attaches to the bottom of one follicle and the other end to the top of an adjacent follicle. Another unit between the same two feathers will have the reverse arrangement (Fig. 1.1). It is evident, therefore, that the contraction of a set of muscles will erect two adjacent feathers and an opposite crossing set will depress the same two feathers. Smooth muscles do not encircle a follicle; there are bundles of elastic tissue that link the smooth muscles to the outer surface of the follicle that contains

within its wall elastic and collagenic connective tissues (Fig. 1.1).

Integumentary Structures

Comb, wattles, ear lobes, beak, scales, claws, spurs, and pipping tooth of chickens, leader (s. snood), carunculate skin and beard of the turkey, and the beak, nail and lamellae (s. strainers) of the duck are specialized integumentary structures. They show the basic plan of the integument found in feathered parts of the body. The leader of the turkey has an erectile-type vascular tissue composed of helicine arteries and sinusoidal capillaries near the surface of the organ. Bundles of smooth muscles extend lengthwise through the leader.

The comb of a chicken has neither helicine arteries nor longitudinal muscles. Between the central connective tissue axis of the comb and the peripheral capillary layer is a broad band of muco-fibrous tissue in the adult male and the laying female chicken. According to Champy and Kritch (1925 and 1926) this mucoid tissue disappears in the capon and in the female out of production. They suggest (1926) that turgor is brought about in the comb of the cock by the production of an edema in the muco-fibrous layer, that this compresses the small, thin-walled veins producing a blood stasis in the sinusoidal capillary layer.

The wattle, like the comb, has a central axis of dense connective tissues bearing many large vessels and nerves. The deep dermal layer is composed of very loose connective tissue and the superficial layer is well vascularized with small vessels. A muco-fibrous layer may be present under the same conditions that produce its presence in the comb. The deep dermal layer of the ear lobe is dense collagenic tissue with fiber bundles running in three directions. The superficial layer is highly vascular even in the white ear lobe of the leghorn. Champy and Demay (1930) suggest that the white coloration of the ear lobe

and some of the caruncles of the turkey are due to a sclerotic condensation of connective tissue.

Scales of birds, like those of reptiles, develop as thickenings of the *stratum corneum*. Between scales the corneal layer is depressed and usually thinner than at the surface of the scale and is more flexible. Large scales may overlap slightly but generally they lie in the same plane as the epidermis. There is continuity of the corneal layer of the scales with that of claws and spurs and the tissue components of the beaks are the same as a large thickened scale.

Only holocrine glands occur in avian skin, the uropygial on the dorsal surface of the tail and the "ear fold" within the external canal (Plate, 1924). The uropygial gland produces a yellow ceruminous secretion that is emptied into a large central cavity and is conveyed to the outside through ducts carried by the uropygial papilla. The secretory units are straight tubules with their closed ends against the connective tissue wall of the gland. Generative cells form a single layer at the periphery of each tubule and as the cells move centrally, lipid spheres form within the cytoplasm. These increase in number and in the cells that contain them enlarge. At the lumen of the tubule the cells disintegrate, releasing their contents.

SKELETAL SYSTEM

Differences in Skeleton Between Birds and Mammals

There are many differences in the skeletal system of birds and that of mammals. For example, most mammals have 7 cervical vertebrae, whether the neck is short as in a whale or long as in a giraffe, but in birds the number varies from 8 to 25 and usually has a relationship to the length of the neck. The total number of vertebrae in birds varies from about 40 to over 60 (Bellairs and Jenkin, 1960; Romanoff, 1960). In mammals only thoracic vertebrae bear movable ribs, but in birds cervical and

lumbar vertebrae may carry movable ribs as well as those of the thorax. The pubic bones of birds are directed posteriorly instead of anteriorly and are spread far apart, so that a *symphysis pubica* is absent. Extensive ankylosis of dorsal vertebrae is common in birds but in mammals is found only in the sacral region. The differences between the head skeleton of birds and mammals are indeed numerous, and are related to their reptilian progenitors. (For a good general reivew of the avian skeletal system, see Reynolds, 1913.)

Axial Skeleton

The neck and tail are flexible but the body (thorax, lumbar, and sacral regions) has only one movable vertebra throughout its length in the chicken. The relatively rigid body gives a firm fuselage for the wings and landing gear.

There are 16 or 17 cervical vertebrae, beginning with the atlas (Fig. 1.4). The last of these in older speeimens may be partially or entirely fused with ankylosed thoracic vertebrae. The centrum bears a heterocoelous articulation, namely saddle-shaped, in which the anterior face is concave horizontally and convex vertically but this changes to a nearly acoelous condition in the coccygeal vertebrae.

On the dorsal side of each cervical vertebra there is a pair of prezygapophyses with articular surfaces upward and a pair of postzygapophyses with articular surfaces downward. Through the series of cervical vertebrae the right and left components of the neural spine may be fused, separated, or absent. The right and left hypapophyses (ventral processes from the centrum) may be fused in the mid-line or remain apart. The hypapophysis of the last cervical is often joined with that of the succeeding fused thoracic vertebrae. On the lateral surface, close to the fore margin of each cervical vertebra except on the atlas and axis, are two transverse processes encircling the vertebral artery, forming the transverse foramen. The processes

are derived from a dorsal component, the diapophysis, and a ventral component, the pleurapophysis. The latter, on some vertebrae, carries a styloid process projecting posteriorly. The diapophysis carries an articular surface for the tubercle of the movable rib and the pleurapophysis forms the vertebral member (dorsal part) of the rib, including the head. In a skeleton of a chicken 6 to 8 weeks of age, a plate at the side of the centrum, called the parapophysis, supports the pleurapophysis and in older birds fuses with it, or becomes the facet area for the head of the movable rib.

Mivart (1895), Howard (1929), and Zusi (1962) are some who have presented terminology for the adult condition of the vertebrae of birds but this is best interpreted through studies of embryology (Piiper, 1928; Williams, 1942; Romanoff, 1960) and comparative anatomy (Goodrich, 1958).

The vertebrae and their lateral processes, the ribs and sternum, form a skeletal enclosure for thoracic viscera. The last two cervical vertebrae bear movable vertebral ribs. Arbitrarily the true thoracic ribs generally have been considered as those that have both vertebral and sternal members and together they form a complete rib that extends from a vertebra to the sternum. (In mammals the costal cartilage represents the sternal member.) Uncinate processes, directed posteriorly, are carried by the vertebral member of the last cervical and all of the thoracic ribs but not by the lumbar rib at the end of the series. These processes provide origin for serratus muscles to the scapula and attachments for intercostal muscles. The lumbar ribs (posterior floating ribs) are either incomplete or articulated with a caudal thoracic rib (rather than with the sternum). The first pair of lumbar ribs is complete and the second may be nearly complete or a small rudiment.

On the basis of its ribs, the chicken has 4 (sometimes 5) thoracic vertebrae (Fig. 1.4). The last cervical and the first 3 thoracic are ankylosed in older birds. The hypapophysis lies between the right and left lungs and forms an origin for ventral neck muscles. The last thoracic vertebra is movable.

The 4 lumbar, 5 sacral, and the first 6 caudal vertebrae are fused into an immobile dorsal plate, the synsacrum. The separate vertebrae are clearly shown in a two-month-old chicken. The fused plate, along with the pelvic arch, composed of ilium, ischium, and pubis, forms the pelvis. The lumbar vertebrae have robust dorsal and ventral processes (diapophyses and pleurapophyses respectively); the last in the series is especially heavy. The first in the series bears a pair of lumbar ribs. The sacral vertebrae have dorsal but lack ventral processes and may be so completely fused in older birds that they are difficult to count but may be identified by the foramina through which the sacral nerves emerge. Caudal vertebrae form the tail; the 6 incorporated within the synsacrum have both dorsal and ventral lateral processes. Posterior to these, there are 6 coccygeal (posterior caudal) vertebrae and a terminal flattened bone, the pygostyle, representing a fusion of about 6 additional caudal vertebrae. The articular surfaces of the centra of the free coccygeal vertebrae allow limited movement. These vertebrae, except the last, have flat transverse processes. Sometimes these processes of the first coccygeal vertebra articulate with the ilia. A chicken, therefore, has a total of approximately 42 vertebrae, exclusive of the pygostyle.

Pectoral Girdle and Wing

The pectoral arch, composed on each side of scapula, coracoid, and clavicle is a tripod-shaped structure with the shoulder joint at its apex (Fig. 1.4). The right and left clavicles are fused ventrally by the hypocleidium and united to the sternal spine by a ligament. Lateral to the spine is a deep transverse groove into which the broad base of the coracoid is implanted and which allows limited antero-posterior movements. The dorsal end of the clavicle articulates on its lateral face with the head

are derived from a dorsal component, the diaphysis, and a ventral component, the pleurapophysis. The latter, on some vertebrae, carries a styloid process projecting posteriorly. The diapophysis carries an articular surface for the tubercle of the movable rib and the pleurapophysis forms the vertebral member (dorsal part) of the rib, including the head. In a skeleton of a chicken 6 to 8 weeks of age, a plate at the side of the centrum, called the parapophysis, supports the pleurapophysis and in older birds fuses with it, or becomes the facet area for the head of the movable rib.

Mivart (1895), Howard (1929), and Zusi (1962) are some who have presented terminology for the adult condition of the vertebrae of birds but this is best interpreted through studies of embryology (Piiper, 1928; Williams, 1942; Romanoff, 1960) and comparative anatomy (Goodrich, 1958).

The vertebrae and their lateral processes, the ribs and sternum, form a skeletal enclosure for thoracic viscera. The last two cervical vertebrae bear movable vertebral ribs. Arbitrarily the thoracic ribs generally have been considered as those that have both vertebral and sternal members and together they form a complete rib that extends from a vertebra to the sternum. (In mammals the costal cartilage represents the sternal member.) Uncinate processes, directed posteriorly, are carried by the vertebral member of the last cervical and all of the thoracic ribs but not by the lumbar rib at the end of the series. These processes provide origin for serratus muscles to the scapula and attachments for intercostal muscles. The lumbar ribs (posterior floating ribs) are either incomplete or articulated with a caudal thoracic rib (rather than with the sternum). The first pair of lumbar ribs is complete and the second may be nearly complete or a small rudiment.

On the basis of its ribs, the chicken has 4 (sometimes 5) thoracic vertebrae (Fig. 1.4). The last cervical and the first 3 thoracic are ankylosed in older birds. The hypapophysis lies between the right and left lungs and forms an origin for ventral neck muscles. The last thoracic vertebra is movable.

The 4 lumbar, 5 sacral, and the first 6 caudal vertebrae are fused into an immobile dorsal plate, the synsacrum. The separate vertebrae are clearly shown in a two-month-old chicken. The fused plate, along with the pelvic arch, composed of ilium, ischium, and pubis, forms the pelvis. The lumbar vertebrae have robust dorsal and ventral processes (diapophyses and pleurapophyses respectively); the last in the series is especially heavy. The first in the series bears a pair of lumbar ribs. The sacral vertebrae have dorsal but lack ventral processes and may be so completely fused in older birds that they are difficult to count but may be identified by the foramina through which the sacral nerves emerge. Caudal vertebrae form the tail; the 6 incorporated within the synsacrum have both dorsal and ventral lateral processes. Posterior to these, there are 6 coccygeal (posterior caudal) vertebrae and a terminal flattened bone, the pygostyle, representing a fusion of about 6 additional caudal vertebrae. The articular surfaces of the centra of the free coccygeal vertebrae allow limited movement. These vertebrae, except the last, have flat transverse processes. Sometimes these processes of the first coccygeal vertebra articulate with the ilia. A chicken, therefore, has a total of approximately 42 vertebrae, exclusive of the pygostyle.

Pectoral Girdle and Wing

The pectoral arch, composed on each side of scapula, coracoid, and clavicle is a tripod-shaped structure with the shoulder joint at its apex (Fig. 1.4). The right and left clavicles are fused ventrally by the hypocleidium and united to the sternal spine by a ligament. Lateral to the sternal is a deep transverse groove into which the broad base of the coracoid is implanted and which allows limited antero-posterior movements. The dorsal end of the clavicle articulates on its lateral face with ...
of the coracoid. A space formed by the heads of the 3 bones of the pectoral girdle is the triosseal canal, through which passes the tendon of the supracoracoid muscle, the chief action of which is to elevate the wings. A large cartilaginous pad forms the glenoid fossa supported on the articular surfaces of the coracoid and scapula.

The sternum is composed of a narrow, median plate with antero- and posterolateral processes and a deep, triangular keel (carina) (Fig. 1.4). The thoracic ribs are implanted on the costal margin of the sternum between the basal ends of these processes. The posterior process of the chicken has two horns, median and lateral, and these form boundaries for the median and lateral notches. The sternal plate has a sternal spine and the keel has a carinal apex at the anterior extremities; between the two is a C-shaped margin designated by Howard (1929) as the anterior carinal margin The sternum shape is extremely variable among birds (Knopfli, 1918)

The bones of the wing are homologous with those of the arm and hand of other tetrapods, and the humerus, radius, and ulna are readily recognizable. The anterior margin of the proximal end of the humerus has a triangular flange, the large deltoid crest and posterior margin has a tuberosity, the bicipital crest (Fig. 1.4) that carries a large pneumatic foramen on its medial surface. The humeral diverticulum of the interclavicular air sac enters the humerus through this foramen (Fig. 1.8). At the distal end of the humerus are the radial and ulnar condyles, separated by an intercondylar furrow. Ect- and entepicondyles and their prominences lie dorsal and ventral to the trochlea along the edge of the bone. Several extensor and flexor muscles of the forearm have their origin from these tuberosities. The wrist bones of the hand have been reduced to a radiale (s. os scapholunatum) and an ulnare (s. os cuneiforme) in the adult but additional wrist bones are present in the embryo. During growth and development

some of the distal carpals fuse with the 3 metacarpals to form the carpometacarpus, the largest bone of the hand. (See Romanoff, 1960, for review of development.) In young chickens the unfused carpal bones may be mistaken for the epiphyses of the metacarpals.

Embryologic studies have provided evidence that the avian hand has retained digits 2, 3, and 4, having lost the first and last digits. The short digit on the anterior edge of the wing supporting the 3 to 4 alular remiges is frequently labeled "thumb (s. pollex)" whereas actually it is the second digit (index finger). Departure from the earlier concept of digits 1, 2, and 3 was brought about by the convincing embryologic studies of Montagna (1945) and Holmgren (1955) and a review by Romanoff (1960).

The bony knob at the base of the index finger is metacarpal 2 on which is inserted the tendons of propatagial muscles, m. extensor metacarpi radialis and m. extensor indicis longus (s. m. extensor pollicis longus) (Hudson and Lanzillotti, 1955). The metacarpal bones are fused with a long space between metacarpals 3 and 4. Metacarpals 2 and 3 bear 2 phalanges, and metacapal 4 bears 1 in the chicken. The distal phalanx of digit 2 bears a short claw in chickens but not in turkeys (Fisher, 1940).

Pelvic Girdle and Extremity

The pelvis is a compound structure composed of the synsacrum and bones of the pelvic girdle. (See Lebedinsky, 1913, and Howard, 1929 for names of parts.) The acetabulum and its adjacent processes mark the division between anterior and posterior parts of the pelvis. The preacetabular part of the ilium is a thin, spoon-shaped plate, the medial margin of which is the crest that extends caudolaterally to the iliolateral process above the acetabulum. The postacetabular part lies in two planes. The medial portion joins the

synsacrum in forming a horizontal plate and the lateral portion with the ischium forms the side wall of the pelvic girdle. The fusion of these two bones is interrupted by a large, elongate ilioischiatic fenestra. Immediately above the acetabulum is the antitrochanter derived from both ilium and ischium. Below and forward the well-developed pectineal process of the ilium is present, to which is attached the ambiens muscle. The ventrocaudal extension of the ischium has been named the ischiatic process (s. ischial angle).

The pubis is a long, slender bone that arises from the ventral part of the acetabulum, and extends beyond the ischium where it curves toward the median plane. Anteriorly the pubis is separated from the ischium by the obturator foramen and posteriorly by the ischiopubic fenestra. The interpubic space varies with the sex of the bird and is widest in laying females. On the ventral side of the pelvic arch are several cavities; lateral to the lumbar vertebrae are the lumbar foveae; caudal to this is an extensive iliac fossa (s. renal depression), separated into anterior and posterior parts at the level of the lateral process of the first caudal vertebra. The fossa continues to the iliocaudal spine but its caudal part is separated from the viscera by the planum anale which has as its cephalic boundary the conspicuous posterior ischiosacral crest.

The thighs of birds are closely pressed against the side of the trunk and in grebes, penguins, and loons only the part of the leg beginning at the knee is distinctly separated externally. The femur of the fowl is sufficiently similar to that of mammals so that its principal parts are readily recognizable, although homologies of the trochanters are controversial (Howell, 1941).

The distal end of the femur articulates medially with the head of the tibiotarsus, and laterally with the head of the fibula. The fibula ends about one-fourth of the distance short of the tarsal (hock) joint.

The knee includes a patella as in mammals. Anterior to the head of the tibiotarsus are sharp ridges, the external (outer) and internal (inner) cnemial crests, to which are attached both thigh and leg muscles. Parker (1884–94) considers these crests to epiphyses.

There are no free tarsal bones in the adult fowl; during development and growth these have fused with the tibia proximally and the metatarsus distally (Nielsen, 1963). Therefore, the intertarsal (hock or ankle) joint involves only tarsal bones rather than an articulation between the long bone of the leg and the ankle bones. During the first few months after hatching the proximal tarsal bone remains as a separable cap on the end of the tibia and as in the arm, superficially resembles an epiphysis. The possible conversion of a sesamoid into a traction epiphysis has been described by Barnett and Lewis (1958).

The tibial cartilage on the distal posterior surface of the tibiotarsus forms a restraining groove for the tendons that extend the foot and flex the toes. The medial part of this cartilage is ossified in older chickens. On the proximal posterior surface of the tarsometatarsus is located the hypotarsus, a separate bone in the young bird that later unites with the tarsometatarsus. It also by its tendinal canal and its ecto- and endocalcaneal ridges separates and guides the tendons for numerous flexor muscles of the toes.

The fifth toe is absent in all birds, but most species have retained 1 to 4 (one or more supernumerary toes are present in several breeds of chicken). A short first metatarsus (accessory metatarsus) is located at the base of the hallux. The distal end of the tarsometatarsus is divided into its original 3 component bones, each articulating with a basal phalanx by a ginglymus (hinge) joint. In many birds each toe has one more phalanx than its digit number; the hallux has 2; the second toe, 3; the third toe, 4; and the fourth toe, 5. Most
FIG. 1.5 — Bones of the skull, face, jaws, and hyoid of an adult male turkey. b., bone; n., nerve; proc., process; Reg., Region. (From USDA.)

of the terminal phalanx forms a bony core for the claw.

Skeleton of the Head

The head includes cranium, face, jaws, and hyoid. The bones of the head reflect particularly well the reptilian ancestry of birds. The cranial bones in the adult are completely fused and most of the suture lines disappear (Fig. 1.5), but the separate bones of the head can clearly be distinguished in the young specimen, the development of which has been described by Jollie (1957).

The premaxilla has 3 processes, maxillary, palatine, and frontal, all directed caudally. The nasal bone lies laterally on the frontal process (s. nasal process) of the premaxilla and has two processes of its own, superior and inferior. The maxilla in birds is relatively small; there are 2 processes, a zygomatic to the jugal bar (upper jaw) and a palatine.

The prefrontal bone and its orbital process have been designated the lacrimal

bone by many, but Gregory (1920) has presented evidence that mammals retained the reptilian lacrimal, losing the prefrontal, and that the reverse took place in the evolution of birds. The orbital process lies between the nasal and orbital cavities and supports the attachments for the oblique eye muscles. The prefrontal bone and its process are highly variable in size and shape among various species of birds.

The paired frontal bones are large; their anterior ends as well as the caudal tips of the premaxillae rest upon the upper end of the mesethmoid. The fused parietals located at the caudal part of the cranium are flanked by a pair of squamosal bones and caudally by the base of the head, a median supraoccipital and a pair of exoccipital bones. These, with the basioccipital bound the foramen magnum. The occipital condyle is a single median structure, in contrast to the paired condition in mammals.

The interorbital septum (s. ethmoid bone) is the thin partition that separates

right and left orbital cavities. The palpable posterior boundary of the orbit is a pointed postorbital process of the alisphenoid frequently fused with the anterior process of the squamosal bone. The ear has a complicated osteology; its walls and parts are derived from the epiotic and episthotic bones on the inner surface of the supraoccipital, and the prootic beneath the squamosal. The columella and semicircular canals are discussed later.

The quadrate bone, said to be homologous with the incus of mammals, has two processes and is the point around which most actions of the jaw pivot. The squamosal process articulates with the prootic bone. The orbital process of the quadrate articulates with the pterygoid and this in turn with the palatine. The body of the quadrate articulates with the quadratojugal and suspends the lower jaw. The upper jaw is elevated at the frontonasal hinge by means of a rotating movement of the quadrate, which is transmitted through the jugal bars and the palatines (Zusi, 1962). Movements of the quadrate also act on the lower jaw.

The embryonic components of the lower jaw—articular, angular, surangular, prearticular, splenial, and dentary—are fused early in life, but some of these are still distinguishable in the adult. It is characteristic of birds that the lower jaw, approximately in the center of its lateral surface, is perforated by a mandibular foramen.

The hyoid is composed of a group of bones arranged as a median axis and a pair of long, slender horns that curve upward around the base of the head. In the mid-line the basihyal articulates anteriorly with the paraglossal, a structure unique in birds (Bellairs and Jenkin, 1960) and posteriorly with the urohyal. The horns, composed of a basal ceratobranchial and a distal epibranchial, articulate on the sides of the basihyal. The hyoid supports the tongue and its musculature.

A ring of 12–16 (median 14) overlapping sclerotic plates embedded in the eyeball encircles the iris (Lemmrich, 1931;

Curtis and Miller, 1938; Nelson, 1942; Jollie, 1957). The variability of number and overlap has been studied by Coulombre et al. (1962). The sclerotic ring in birds is inherited from reptiles. In the chicken and many birds it is composed of small plates but in hawks, owls, and other raptorial species the plates are large and arranged to form a tube.

MUSCULAR SYSTEM

The following enumeration based on the muscles of the whooping crane (Fisher and Goodman, 1955) lists the skeletal muscles in various parts of the body and approximates the number of these muscles present in the chicken:

Head, jaw, and adjacent neck	20
Tongue, hyoid, and trachea	18
Eye globe, lids, and a dermal muscle to the ear	12
Wing and pectoral girdle	48
Leg and pelvic girdle	42
Abdominal and thoracic wall	6
Vertebral column including remaining neck	15
Tail	10
Total	171

Numerous individuals have contributed to our knowledge of avian musculature (Helm, 1881; Shufeldt, 1890; Fürbringer, 1888; Gadow and Selenka, 1891; Mudge, 1902; Boas, 1929; Hudson, 1937; Hudson et al., 1955, 1959, 1964; Fisher, 1916; Berger, 1952; Davids, 1952; Den Boer, 1953; Rooth, 1953; Starck and Barnikol, 1954; Burggraaf, 1954; Burggraaf and Fuchs, 1954, 1955; Fuchs, 1954, 1955; Goodman and Fisher, 1962; Zusi, 1962). Many of these papers include synonymy. The developmental sequence for the muscles of thigh, leg, and foot of the chicken has been studied by Romer (1927) and Wortham (1918), and the development of muscle groups of the wing by Sullivan (1962).

Some muscles of birds have no equivalent in mammals, largely because of differences in skeletal structure and in func-

tions of body parts, for example: the ilium of mammals does not extend in either direction much beyond the acetabular region, whereas in birds the ilium is extremely long. Hence the iliotrochanteric muscles are peculiar to birds and not represented in mammals or at least cannot be definitely homologized (Hudson, 1937). The ambiens muscle, which originates on the pectineal process, is peculiar to birds and reptiles and is absent in mammals. A broad, flat, triangular muscle, the iliotibialis, covers much of the lateral surface of the thigh. It is divisible into anterior, medial, and posterior parts. Gadow (Hudson, 1937) considers the anterior part as absent in mammals, the middle part as homologous with the *m. tensor fasciae latae* of mammals and the posterior part as homologous with the *m. gluteus maximus*. In birds the gastrocnemius has three parts. The external and medial parts may represent the *m. gastrocnemius* of man and the internal part may be homologous with the *m. soleus* of man.

In Fig. 1.6 is shown the superficial muscles visible from the side. The terminology for wing, limb, and girdles follows Hudson (1937) and Hudson *et al.* (1955, 1959, 1964), and that for head, hyoid, neck, and tail has been taken from various authors but mostly from Fisher and Goodman (1955). The names of muscles of breast, shoulder, pelvis, and thigh are presented in Tables 1 and 2 and include a brief statement of origin and insertion of each muscle.

Medial to the eye globe are two muscles in addition to the six found in mammals, i.e., *m. quadratus nictitantis* and *m. pyramidalis nictitantis* that are involved in movement of the nictitating membrane (Fig. 1.7).

The bellies of the muscles of the appendages are concentrated near their respective origins, thus shifting their weight closer to the center of gravity. The reduction of digits in the wing is a second factor in the fusion of muscle masses and their

consequent multitude of origins. Centripetal placement of the muscle masses tends to produce long tendons, and in the legs especially these are guided by well-developed fibrous sheaths, loops, grooves, and canals in bone and cartilage. Sesamoid bones are common and many tendons become ossified.

Breast muscle is composed of fibers of two size groups: the large are light in color, the small are dark. In addition there are many cytochemical differences (Watzka, 1939; George and Naik, 1957, 1958, and 1959; George and Talesara, 1962).

VASCULAR SYSTEM

Heart

The avian heart has its axis in the median plane of the body. Its ventricles are nearly surrounded by the lobes of the liver. Like the mammalian heart, it is four-chambered and the circulation of blood through these chambers is similar in the two classes of vertebrates. Some of the distinctive features of the heart in birds, as found by Kern (1926), Petrén (1926), Uchiyama (1928), and Westpfahl (1961), are as follows: (1) Relative to body weight, it is heavier in birds than in mammals or reptiles, (2) neither a *ductus arteriosus* nor a *ligamentum arteriosum* is present in chickens but both structures have been reported for other species of birds, (3) a distinguishable *fossa ovalis* fails to persist after the closure of the *foramen ovale* in the embryo, (4) plaques of cartilage are normally present in the aorta at the level of the semilunar valves and sometimes in the wall of the adjacent common pulmonary artery, (5) most commonly there are 2 coronary arteries, but 3, 4, and even 5 are frequently present, (6) there are extensive anastomoses between branches of the major coronary arteries, (7) the *Vv. minimae Thebessi* and sinusoids are abundant in the right ventricle, particularly in the septum.

The pericardium is closely applied to the atria and major vessels of the heart but posteriorly around the ventricles and be-

TABLE 1.1

MUSCLES OF BREAST AND SHOULDER
OF THE SINGLE COMB WHITE LEGHORN CHICKEN *

Name	Origin	Insertion
M. latissimus dorsi anterior	Spinous procs. of caudal cerv. vert.	At prox. third of humerus on mid-post. surf.
M. latissimus dorsi posterior	Spinous procs. of thoracic vert.	At prox. third of humerus on mid-post surf caudal to M. lat. dor. ant.
M. latissimus dorsi metapatagialis	A muscle slip from post. end of M. lat. dor. post.	Metapatagial memb. at post. end of humeral tract.
M. rhomboideus superficialis	Under M. lat. dor. From spinous procs. of C_{14} and T_3.	Head and 3/4 of dor. margin of scapula.
M. rhomboideus profundus	Under M. rhomb. sup. From spinous procs. of C_{15} to T_6.	Distal 3/4 of med. surf. of scapula near dor. edge.
M. serratus superficialis anterior	From the vert. memb. of the T_1 rib and possibly C_{17} and T_2.	Tuber. on vent. edge of scapula, 1/4 distance from head.
M. serratus superficialis posterior	From the vert. memb. of T_2–L_2 ribs and unc. procs.	Caudal tip of scapula.
M. serratus superficialis metapagialis	From T_3 rib vent. to unc. proc.	Skin of the metapatagium.
M. serratus profundus	Vert. memb. of C_{17}–T_2 above unc. procs.	Middle 1/3 of med. surf. of scapula.
M. scapulohumeralis anterior	Vent. edge of scapula distal to glenoid facet	Posterovent. surf. of humerus, caudal to pneumatic foramen.
M. scapulohumeralis posterior	Most of lat. surf. of scapula	Posterovent. surf. of humerus on bicipital crest.
M. pectoralis thoracica **	Lat surf of keel, near vent. marg., posterolat. proc. of sternum, sternal ends of T_{2-6} and R ribs, clavicle and hypocleidium.	Ant. surf. of humerus below the distal half of the deltoid crest.
M. supracoracoideus	1. Dorsal part of lat. surf. of keel. 2. Anterolat. surf. of coracoid. 3. Vent. half of memb. on sternal notch. 4. Centr. part of sterno-coraco-clavicular memb.	Through triosseal canal to humerus: 1. Ant. surf. below deltoid crest. 2. Dorsopost. surf. at base of deltoid crest.
M. coracobrachialis anterior	Ant. surf. at dor. end of coracoid (the acrocoracoid).	Ant. surf. of humerus under ant. half of deltoid crest.
M. coracobrachialis posterior	Anterolat. surf. of coracoid and adjacent sternum.	Post. surf. of humerus on int. tuberosity.
M. sternocoracoideus	Lat. surf. of anterolat. proc. of sternum and adj. subcostal area of sternum	Middle third of coracoid on lat. half of post. surf.

tions of body parts, for example: the ilium of mammals does not extend in either direction much beyond the acetabular region, whereas in birds the ilium is extremely long. Hence the iliotrochanteric muscles are peculiar to birds and not represented in mammals or at least cannot be definitely homologized (Hudson, 1917). The ambiens muscle, which originates on the pectineal process, is peculiar to birds and reptiles and is absent in mammals. A broad, flat, triangular muscle, the iliotibialis, covers much of the lateral surface of the thigh. It is divisible into anterior, medial, and posterior parts. Gadow (Hudson, 1937) considers the anterior part as absent in mammals, the middle part as homologous with the m. tensor fasciae latae of mammals and the posterior part as homologous with the m. gluteus maximus. In birds the gastrocnemius has three parts. The external and medial parts may represent the m. gastrocnemius of man and the internal part may be homologous with the m. soleus of man.

In Fig. 1.6 is shown the superficial muscles visible from the side. The terminology for wing, limb, and girdles follows Hudson (1937) and Hudson et al. The names of muscles of breast, shoulder, pelvis, and thigh are presented in Tables 1 and 2 and include a brief statement of origin and insertion of each muscle.

Medial to the eye globe are two muscles in addition to the six found in mammals, i.e., m. quadratus nictitantis and m. pyramidalis nictitantis that are involved in movement of the nictitating membrane (Fig. 1.7).

The bellies of the muscles of the appendages are concentrated near their respective origins, thus shifting their weight closer to the center of gravity. The reduction of digits in the wing is a second factor in the fusion of muscle masses and their consequent multitude of origins. Centripetal placement of the muscle masses tends to produce long tendons, and in the legs especially these are guided by well-developed fibrous sheaths, loops, grooves, and canals in bone and cartilage. Sesamoid bones are common and many tendons become ossified.

Breast muscle is composed of fibers of two size groups: the large are light in color, the small are dark. In addition there are many cytochemical differences (Watzka, 1939; George and Naik, 1957, 1958, and 1959; George and Talesara, 1962).

VASCULAR SYSTEM

Heart

The avian heart has its axis in the median plane of the body. Its ventricles are nearly surrounded by the lobes of the liver. Like the mammalian heart, it is four-chambered and the circulation of blood through these chambers is similar in the two classes of vertebrates. Some of the distinctive features of the heart in birds, as found by Kern (1926), Petrén (1926), Uchiyama (1928), and Westpfahl (1961), are as follows: (1) Relative to body weight, it is heavier in birds than in mammals or reptiles, (2) neither a ductus arteriosus nor a ligamentum arteriosum is present in chickens but both structures have been reported for other species of birds, (3) a distinguishable fossa ovalis fails to persist after the closure of the foramen ovale in the embryo, (4) plaques of cartilage are normally present in the aorta at the level of the semilunar valves and sometimes in the wall of the adjacent common pulmonary artery, (5) most commonly there are 2 coronary arteries, but 3, 4, and even 5 are frequently present, (6) there are extensive anastomoses between branches of the major coronary arteries, (7) the Vv. minimae Thebessi and sinusoids are abundant in the right ventricle, particularly in the septum.

The pericardium is closely applied to the atria and major vessels of the heart but posteriorly around the ventricles and be-

TABLE 12 (continued)

Name	Origin	Insertion
M. femoritibialis externus	Lower half of femur, on lat. surf.	Patella and patellar tendon via femoritibialis medius.
M. femoritibialis medius	Most of ant. and lat. surfs. of femur betw'n trochanter and condyles.	Patella and patellar tendon.
M. femoritibialis internus	Med. surf. of the shaft of the femur.	Medial tibial crest.
M. piriformis pars caudifemoralis pars iliofemoralis	Posterolat. surf. of pygostyle. 1. Ilium caudal to ilioischiatic fenestra. 2. Caudal marg. of ischium.	Med. surf. femur ⅓ dist. distal to head.
M. semitendinosus	1. Edge of iliocaudal spine. 2. Adj. coccygeal vert.	On the ext. cnemial crest, continuing slightly distal to it.
Accessorius semitendinosi	Post. surf. of femur prox. to intercondylar furrow.	Via raphe to the belly of the semitendinosus.
M. semimembranosus	1. Vent. marg. of ischium — most of caudal half. 2. Lat. surf. of pubis opposite ischiatic proc.	Joins tendon of semitendinosus and has same insertion..
M. biceps femoris	Dorsal part of lat. wall of ilium in renal reg. above illioischiatic fenestra.	Tendon passes through biceps loop and inserts on a posterolat. tubercle of fibula ⅓ from prox. end.
M. ischiofemoralis	Most of the lat. surf. of ischium.	Lat. surf. of femur at base of trochanter.
M. obturator externus	1. Betw'n acetabulum and obturator foramen. 2. Vent. to obturator foramen.	Posterior marg. of trochanter.
M. obturator internus	Mult. heads. Inner surf. of ilium, ischium, and pubis, above and caudal to the foramen.	Lat. surf. of trochanter.
M. adductor longus et brevis, pars externa	Laterovent. marg. of ischium in 2nd quarter of marg.	Med. surf. of femur betw'n base of trochanter and the condyles.
M. adductor longus et brevis, pars interna	On pubis below acetabulum and then to laterovent. marg. of ischium to within ¼ of its caudal end.	A line on medial surf. of lower ¾ of femur.

Abbreviations:

adj. = adjacent	lat. = lateral	posteromed. = posteromedial
ant. = anterior	laterovent. = lateroventral	proc. = process
anterolat. = anterolateral	marg. = margin	prox. = proximal

TABLE 1.2

MUSCLES OF PELVIS AND THIGH
OF THE SINGLE COMB WHITE LEGHORN CHICKEN*

Name	Origin	Insertion
M. iliotrochantericus posterior	Lat. surf. of the gluteal ilium except margs, and a triangular area above the acetabulum.	Ant. marg. of the lat. surf. of the trochanter (femur).
M. iliotrochantericus anterior	Ant. ⅔ vent. marg. of gluteal ilium.	Anterolat. surf. of shaft of femur just distal to trochanter.
M. iliotrochantericus medius	Lat. surf. of gluteal ilium just ant. to the acetabulum.	Distal end of anterolat. surf. of trochanter.
M. glutaeus medius et minimus	Triangular area above and ant. to antitrochanter and below iliolat. proc.	Center of lat. surf. of trochanter.
M. iliacus	Depression ant. to pectineal proc.	Posteromed. surf. femur ⅓ dist. distal to head.
M. ambiens	Outer half of pectineal proc.	Lat. side of head of fibula via the heads of the flexor perforatus muscles.
M. sartorius	Ant. part of the crest of the ilium.	1. Med. part of patellar tendon. 2. Ant. tibial crest.
M. iliotibialis	1. Crest of the ilium caudally from origin of sartorius. 2. Dorsal surf. of ilium. 3. Iliocaudal spine. 4. Caudal marg. of ilium and ischium to ischiatic proc.	1. Patella. 2. Lat. part of patellar tendon.

[16]

; Figs. 1.14 and 1.16 and some branches m the cranial mesenteric in Fig. 1.10.

Parietal branches from the aorta supply teries to the ribs, rib spaces, vertebral ructures, and muscles through the *aa. in- rcostales, aa. lumbales, aa. sacrales lat- ales*, and *aa. coccygica laterales*. A pair large vessels in both sexes, *aa. spermati- e internae*, gives branches to the anterior bes of the kidneys and to the adrenal lands. In the female a large median ves- l, *a. ovarica*, supplies the ovary and part the oviduct, the branches of which are own in Fig. 1.16. Other lateral branches pply the remaining lobes of the kidney nd in the female, the lower oviduct. reedman and Sturkie (1963) have investi- ated in detail the arterial and venous upply to the oviduct, and have reviewed he terminology for these vessels, making ome changes. (See page 44 for additional nformation on the vascular system in the emale.)

The most posterior unpaired branch of he aorta is the *a. mesenterica caudalis*, vhich anastomoses with branches from the ranial mesenteric artery. The major ves- els to the leg are the *a. iliaca externa* and . *ischiatica externa*. The external iliac rtery gives rise to about 4 vessels includ- ng the *a. femoralis*. Most of the blood upply to the leg as well as parts of the fe- nale reproductive system comes from the xternal ischiatic artery of which there are bout 22 named branches. (See also Ni- hida, 1963.)

A short distance distal to the caudal nesenteric artery the *a. sacralis medialis* divides into a right and left *a. pudendalis interna* and a median continuation into he tail region as the *a. coccygica media*. The internal pudendal artery gives rise to a branch that supplies the internal obtu- rator muscle and a branch to the bursa and dorsal surface of the cloaca.

A large branch from the intestinal ramus of the pudendal artery parallels the side of the cloaca and enters the *corpus cavernosum* (Barkow, 1829), a body present in male chickens (Fig. 1.14) but not in fe-

males. It consists of a compact mass of capillaries with very little supporting tis- sue instead of the large vascular sinuses found in typical erectile tissue. Peripheral to these are arteries with thick muscular walls. The body has no structural connec- tion with the ejaculatory duct but its caudal tip lies beneath the round body on each side of the phallus.

We recommend that the term, *corpus cavernosum*, be changed to *glomus para- cloacalis* since Barkow's term as used by Gadow (1888) and most other writers identify this name with the large sinus- oidal erectile tissue associated with the phallus or ejaculatory duct. Nishiyama (1955) has used the term, vascular body.

Veins

A recent, comprehensive description of the veins of the chicken is not at present available. The work of Neugebauer (1845) is still a standard reference as well as the book by Gadow and Selenka (1891). Blood from the brain, deep and superficial mus- culature of the head, the ear, and the base of the skull drains by way of about 12 major vessels into the jugular veins. An anastomosis in the region of the hyoid joins the right and left jugulars. Each jugular vein receives many branches from muscle, skin, and organs of the neck by way of about 9 major vessels of which the vertebrals have the most extensive drain- age. Junction of each *v. jugularis* at the base of the neck with the *v. subclavia* forms the *vena cava anterior* (*s. v. brachiocephal- alica*) (IANC, 1956). The subclavian vein receives blood from the wing and anterior part of the thorax by way of the *v. axill- laris*, *vv. pectoris externae*, *v. coracoidea*, and *v. sternalis*. The left anterior vena cava crosses the dorsal surface of the heart to enter the right atrium at a point slightly apart from that of the right anterior vena cava.

Blood from the viscera, body wall, limbs, and tail is brought to the heart through a somewhat complicated system of channels involving two portal systems. The termi-

yond it is drawn out into a large cone that tapers to a point within the ventral mesentery between the liver lobes.

Arteries

In the following discussion the terminology proposed by Westpfahl (1961) has been used for major arteries in the chicken. This author has given an extensive review of nomenclature.

From the base of the aorta at the level of the semilunar valves arise the right and left coronary arteries; each divides into deep and superficial branches. A pair of large vessels, the *aa. brachiocephalicae*, arise from the aorta just anterior to the

pericardial sac; each of these divides into *a. subclavia* and *a. carotis communis* (Fig. 1.17). The *a. subclavia*, in the angle between coracoid and scapula, divides into numerous branches that supply the inner and outer breast musculature and skeleton. The first branch is the *a. sternoclavicularis*, which turns ventrally, crossing the coracoid, to supply the anterior end of the sternum, the lower part of the clavicle, and the larger muscles of the breast. The subclavian then divides into *a. axillaris* and several *aa. thoracicae*. The former supplies all the wing muscles and skeleton by way of fourteen named arteries and several lesser branches. The latter supply the

sternum, ribs, and associated muscles. (See also Nishida, 1960.)

Two vessels arise from opposite sides of the common carotid artery near its point of origin, the a. oesophagica ascendens and the a. bronchialis. The former vessel sends branches to several important organs; those to the thyroid gland are the a. thyroidea cranialis and a. thyroidea caudalis. As shown in Fig. 1.17, additional branches supply the parathyroids and ultimobranchial bodies. The carotid body lies between the carotid artery and the nodose ganglion close to the cranial or to the caudal parathyroid gland (Chowdhary, 1955) and measures $0.8 \times 0.5 \times 0.5$ mm. The adventitial tissue of the small artery that enters the carotid gland has continuity with the capsule of the gland. Two types of cells are present: large, granular argyrophils and small, darkly staining, nongranular, nonargyrophilic cells. These cells extend into the tunica media of the nutrient vessel, and even into the wall of the adjacent carotid artery; the junction of these vessels forms the carotid sinus.

Each ascending esophageal artery supplies trachea, crop, and in the region of the 4th cervical vertebra anastomoses with a descending esophageal artery, from the external carotid by way of the laryngeal artery. The bronchial artery gives branches to the lower esophagus, trachea, syrinx, and primary bronchi. At the level of the thyroid gland (Fig. 1.17) arises the a. vertebralis which divides into ascending and descending branches that course through the foramina transversaria. An important branch is the a. comes nervi vagi and a lesser branch passes to the muscles and skin of ventral neck and shoulder. The carotid vessel continues forward from the level of origin of the vertebral artery along the ventral side of the cervical vertebrae. Fleming (1926) and Westpfahl (1961) along with others, name it the common carotid. Glenny (1955) and others on the basis of its embryology call it the internal carotid and Baumel (1963) has used the name dorsal carotid. The common carotid

divides at the level of the intervertebral space of the second and third vertebrae into a. carotis externa and a. carotis interna.

The external carotid has the following major branches: a. occipitalis, a. laryngica, a. auricularis, a. facialis, and a. maxillaris, each with smaller branches distributed to the structures in these named regions. The internal carotid enters the skull posterior to the external ear canal. A large branch, a. ophthalmica externa, supplies the deep musculature of the head and a small a temporalis supplies the skin. Another branch, a. alveolaris inferior, follows the mandibular nerve through the masseter muscle, supplies the palate and throat, and extends to the nasal cartilage. The a ophthalmica externa is a large branch distributed to the eyelids, nictitating membrane, retina, eye muscles, and glands of the orbital space, and to the plexus temporalis that lies in the depression of the skull above the ear opening, and according to Gadow and Selenka (1891), arises between the maxillary and mandibular branches of the trigeminal nerve.

The internal carotid gives off an a. sphenoidea before entering the cranial cavity and then supplies numerous vessels in and around the brain, some of which terminate on the upper lid and nose. Baumel (1962) found that the encephalic arteries of the pigeon were consistently asymmetric in size, arrangement, and distribution; and the illustrations by Kitoh (1962) would indicate that asymmetry was present in the chicken also.

The arteries to the viscera, legs, and tail are branches of the descending aorta. The most anterior of these, the a. coeliaca, is a median, ventral vessel that supplies blood to the esophagus, proventriculus, gizzard, liver, spleen, pancreas, and duodenum. An adjacent median branch from the aorta, a mesenterica cranialis, anastomoses with a branch of the coeliac and vascularizes about three-fourths of the intestine including the proximal ends of the caecae. The branches of the descending aorta are shown

in Figs. 1.14 and 1.16 and some branches from the cranial mesenteric in Fig. 1.10.

Parietal branches from the aorta supply arteries to the ribs, rib spaces, vertebral structures, and muscles through the *aa. intercostales, aa. lumbales, aa. sacrales laterales,* and *aa. coccygica laterales.* A pair of large vessels in both sexes, *aa. spermaticae internae,* gives branches to the anterior lobes of the kidneys and to the adrenal glands. In the female a large median vessel, *a. ovarica,* supplies the ovary and part of the oviduct, the branches of which are shown in Fig. 1.16. Other lateral branches supply the remaining lobes of the kidney and in the female, the lower oviduct. Freedman and Sturkie (1963) have investigated in detail the arterial and venous supply to the oviduct, and have reviewed the terminology for these vessels, making some changes. (See page 44 for additional information on the vascular system in the female.)

The most posterior unpaired branch of the aorta is the *a. mesenterica caudalis,* which anastomoses with branches from the cranial mesenteric artery. The major vessels to the leg are the *a. iliaca externa* and *a. ischiatica externa.* The external iliac artery gives rise to about 4 vessels including the *a. femoralis.* Most of the blood supply to the leg as well as parts of the female reproductive system comes from the external ischiatic artery of which there are about 22 named branches. (See also Nishida, 1963.)

A short distance distal to the caudal mesenteric artery the *a. sacralis medialis* divides into a right and left *a. pudendalis interna* and a median continuation into the tail region as the *a. coccygica media.* The internal pudendal artery gives rise to a branch that supplies the internal obturator muscle and a branch to the bursa and dorsal surface of the cloaca.

A large branch from the intestinal ramus of the pudendal artery parallels the side of the cloaca and enters the *corpus cavernosum* (Barkow, 1829), a body present in male chickens (Fig. 1.14) but not in fe-

males. It consists of a compact mass of capillaries with very little supporting tissue instead of the large vascular sinuses found in typical erectile tissue. Peripheral to these are arteries with thick muscular walls. The body has no structural connection with the ejaculatory duct but its caudal tip lies beneath the round body on each side of the phallus.

We recommend that the term, *corpus cavernosum,* be changed to *glomus paracloacalis* since Barkow's term as used by Gadow (1888) and most other writers identify this name with the large sinusoidal erectile tissue associated with the phallus or ejaculatory duct. Nishiyama (1955) has used the term, vascular body.

Veins

A recent, comprehensive description of the veins of the chicken is not at present available. The work of Neugebauer (1845) is still a standard reference as well as the book by Gadow and Selenka (1891). Blood from the brain, deep and superficial musculature of the head, the ear, and the base of the skull drains by way of about 12 major vessels into the jugular veins. An anastomosis in the region of the hyoid joins the right and left jugulars. Each jugular vein receives many branches from muscle, skin, and organs of the neck by way of about 9 major vessels of which the vertebrals have the most extensive drainage. Junction of each *v. jugularis* at the base of the neck with the *v. subclavia* forms the *vena cava anterior (s. v. brachiocephalica)* (IANC, 1956). The subclavian vein receives blood from the wing and anterior part of the thorax by way of the *v. axillaris, vv. pectoris externae, v. coracoidea,* and *v. sternalis.* The left anterior vena cava crosses the dorsal surface of the heart to enter the right atrium at a point slightly apart from that of the right anterior vena cava.

Blood from the viscera, body wall, limbs, and tail is brought to the heart through a somewhat complicated system of channels involving two portal systems. The termi-

nology for the veins in the kidney region has been taken from Spanner (1925). (See also Portmann, 1950.) A pair of *vv. hypogastricae* (*s. vv. iliacae internae*) drain blood from the tail and caudal parts of the body. At the posterior end of the kidney they are joined by an anastomosis that receives in the mid-line the *v. coccygomesenterica* collecting blood from the terminal end of the digestive tract (Fig. 1.15).

The hypogastric, coccygomesenteric, ischiatic, and external iliac veins contribute blood to the renal portal vein (*v. renalis afferens*). Beyond the capillaries, the blood is recollected in the *v. renalis efferens*, a prominent vein on the ventral side of the kidney. Near the anterior end of the organ, the pair of efferent veins unite to form the *vena cava inferior*. A horseshoe-shaped valve intervenes between the continuation medially of the external iliac vein and the efferent vein; this valve is under the control of the autonomic system Sperber (1960) observed that blood of the renal portal system was distributed to the tubules only and the glomeruli received only arterial blood.

The posterior vena cava ascends to the heart through the right liver lobe. Before entering the right atrium it receives the *vv. hepaticae* which drain the liver. At the atrium its entrance is guarded by the right and left sino-atrial valves, which also function to close the openings from the right and left anterior venae cavae.

Lymphatic Vessels

Significant contributions to the anatomy of the lymphatic system of the pigeon and fowl have been made by Lauth (1824), Josifoff (1930), Baum (1930), and Dransfield (1944, 1915). (See Baum and Trautmann, 1933, for a brief review.) The channels associated with the major visceral arteries and veins are illustrated by Gadow and Selenka (1891) Lymph hearts, characteristic of fish, amphibia, and reptiles, may be present in some birds but are absent in most species. They have been found in chick embryos but not in adult birds.

Lymph vessels, possessing valves, are present in all classes of vertebrates but birds have fewer than mammals, and the number of vessels appears to decrease with age in birds. In the peripheral structures of the body the lymph vessels closely follow the veins or sometimes both veins and arteries; in the visceral parts of the body the lymph vessels follow the arteries but in the heart they follow neither. Lymphatic vessels are found in all parts of the body, skin, muscles, joints, bone marrow, and even in the follicles of remiges and rectrices. Only a few channels are present in the liver, and in the spleen these are limited to the capsule.

Lymph drainage from head, neck, and part of the shoulder follows the jugular veins into which vessels it empties on the right and left sides shortly anterior to the subclavian veins. Lymph drainage from the remainder of the body converges to the thoracic ducts on each side of the aorta and empties into the right and left anterior venae cavae.

Lymph nodes are generally absent in birds except that a few may be found in ducks, geese, and some other aquatic birds in the cervical and caudal regions of the body. Occasionally thymus lobes have been mistaken for lymph nodes. Plexus or rete formation along lymph channels has been found in all classes of vertebrates, although in only a few locations in mammals. These lymph plexuses in non-mammalian classes have been regarded as homologous with lymph nodes of mammals because they occur in such areas as submaxillary, axillary, inguinal, popliteal, abdominal, and similar regions (Dransfield, 1944).

The histology of lymph nodes in aquatic birds has been described by Fleury (1902), Pensa (1907), Jolly (1910), and its embryology by Further (1913). The rete mirabile of the gland is demonstrated in its development. Some have suggested that the lymphoid accumulations found concentrated to various degrees in the avian body were equivalent to mammalian lymph nodes

(Kihara and Naito, 1933; Kondo, 1937; Biggs, 1957). To Lucas (1951), Lucas *et al.* (1954), Denington and Lucas (1960), and Oakberg (1950), these are ectopic lymphoid foci, and are probably centers of reaction to extrinsic pathogenic and nonpathogenic stimuli. There are, of course, normal concentrations of lymphoid tissues such as those of thymus, spleen, cloacal bursa, and follicles within the intestinal wall. It is questionable to these authors if lymphoid accumulations are normally present in the bone marrow of the chicken, although they are so regarded by Kanesada (1956).

Limitations of space prevent a résumé of vascular histology. Morphology of blood cells in various stages of development has been presented by Lucas and Jamroz (1961).

NERVOUS SYSTEM

Central Nervous System

The same 3 meninges are present in birds as in mammals (Hansen-Pruss, 1923). Between the periosteum lining the vertebral canal and the dura mater (*pachymeninx*) are scattered epidural spaces and beneath this membrane are subdural spaces. The *leptomeninx* is composed of arachnoid membrane, arachnoid trabeculae crossing the subarachnoid space, and the pia mater. The last closely invests the brain and spinal cord and carries the vascular supply to these tissues. *Ligamentale denticulata*, present in each segment of the cord and composed of duralike connective tissue, suspend the cord transversely between dura and pia. The subarachnoid space carries the cerebrospinal fluid. The space extends caudally as far as the sinus rhomboidalis and anteriorly as far as the prosencephalon, thus spreading over the dorsal and lateral portions of the brain.

The embryonic development of the plexuses and cerebrospinal fluid has been followed in the chick from the third to the ninth day of incubation (Cohen and

Davies, 1937). The extensive thin roof of the fourth ventricle permits the passage of fluid from the cerebrospinal canal to the embryonic meningeal tissues.

The axis of the brain in relation to the axis of the skull varies a full 90° among various species of birds (Cobb, 1960; Portmann and Stingelin, 1961) and is associated with the position and size of the orbit. The brain of the chicken nearly parallels the head axis.

The ratio of the size of the olfactory bulb to the cerebral hemisphere varies from 5 to 33 per cent. The ratio for the turkey is 13 per cent. The sense of smell in birds is apparently less than in mammals and among avian species it is variable (Cobb, 1960). The bulb contains a cavity continued from the lateral ventricle of the hemisphere.

The cerebral hemispheres are considerably larger in birds than in reptiles, yet nearly all of the avian hemisphere is homologous to the basal nuclei of the mammalian brain. On the dorsal surface is a groove (vallecula) arising from the median fissure and extending laterally and posteriorly (Fig. 1.7). The sagittal elevation medial to the vallecula represents the neopallium (hyperstriatum) that perhaps is equivalent to the mammalian neocortex. A small area at the lateral surface of the avian hemisphere, called the palaeopallium, represents the well developed olfactory lobe (pyriform area) of mammals. The major cavity of the ventricle lies adjacent to the median wall of the hemisphere but in the posterior part it is a flattened cavity that extends to the lateral side of the hemisphere and at the posterior pole it separates the neostriatum from the peripheral portion. The chorioid plexus is limited to the caudo-ventral portion of the ventricle.

The diencephalon, located between the cerebral hemispheres and the laterally placed optic lobes, carries on its ventral surface the optic chiasma and the pituitary. The large thalamus is a product of the sensory alar plate, and only the small

hypothalamus is derived from the motor basal plate. The internal architecture of the diencephalon and some nuclei of the telencephalon and mesencephalon is given in detail by Huber and Crosby (1929). Recently van Tienhoven and Juhasz (1962) have prepared a brief atlas of similar centers for the chicken. Jungherr (1915) has identified the nuclei of the mesencephalon. The embryology of the corpus striatum and pallial layer has been given in detail by Haefelfinger (1958) and the evolutionary divergences by Stingelin (1958).

The morphology of the avian cerebellum has been exhaustively studied by Larsell (1948) and Larsell and Whitlock (1952) and briefly summarized by Portmann and Stingelin (1961). Some of the parts are labeled in Fig. 1.7. The medulla of birds is well developed in the vestibular region, and associated with this is a well-developed Deiter's nucleus receiving fibers from the cerebellum. Pontine fibers and pontine nuclei are well developed also. The development of the hypoglossal nerve and its associated nuclei is related to the utilization of the tongue; thus it varies among different species of birds.

The spinal cord lies within the neural canal of the vertebral column and extends from the medulla to the last free vertebra of the tail. The embryonic retraction of the spinal cord, characteristic of mammals, does not occur in birds and there is no cauda equina. Huber (1936) who has described the internal and external features of the cord in the pigeon lists in that species 39 pairs of spinal nerves. We identify approximately 42 in the chicken. Enlargements of the cord are present in the regions of the plexuses—brachial, lumbar, ischiatic, and pudendal (Goller, 1962).

The intumescentia lumbalis (s. glycogen body) fills a rhomboid sinus in the dorsal half of the spinal cord in the area of the ischiatic plexus. It is a structure peculiar to birds. The details of its development have been reported by Ganfini (1950) and De Gennaro (1959) as observed in the chicken embryo during the seventh to the thirteenth day of incubation. There is first an invasion of meningeal vessels into the ependymal cone, then a swelling of the cells and the body expands laterally against the neural portion of the cord. The leptomeninx lies outside the sinus rhomboidalis. The spinal canal remains closed beneath the glycogen body. Therefore the sinus does not represent a failure of the embryonic neural ridges to close but is rather a specialized modification of the cells of the dorsal ependyma and alar plate. Dickson and Millen (1957) determined that the glycogen body is partly intrapial and partly subpial; the latter portion surrounds the central canal.

A marginal paragriseal column extends most of the length beneath the lateral surface of the cord and is visible grossly in the region of the ischiatic plexus.

Cranial and Spinal Nerves

Birds have 12 cranial nerves as do mammals; the existence of an accessory nerve in birds has been questioned by some (Van Tyne and Berger, 1959) but our dissections (Fig. 1.7) agree with those of Cords (1904). N. olfactorius (I) arises from the olfactory bulb and terminates in the superior concha. N. opticus (II) arises from the optic chiasma beneath the thalamus and passes laterally to enter the medioventral part of the optic globe. N. oculomotorius (III) arises from the mesencephalon close to the mid-line and innervates the superior, anterior, and inferior recti and the inferior oblique muscles. The ciliary ganglion, located in the angle between superior and inferior rami of the oculomotor nerve, innervates the pecten, and the ciliary zone. The ganglion receives a branch from the ophthalmic nerve of the trigeminal. (See Carpenter, 1906, for details of the development of nerves in this area.)

The small n. trochlearis (IV) arises from the dorsal side of the brain and passes down between the optic lobe and the cerebellum to innervate the superior oblique muscle. Cords (1904) describes a communi-

cating branch with the trigeminal that we did not observe.

The origin of n. trigeminus (V) from the floor of the brain as well as the semilunar ganglion is partly covered by the optic lobe. The ophthalmic nerve, the first branch of the trigeminal, extends forward along the ventral edge of the cerebral hemispheres and thence laterally along the superior rectus and the superior oblique muscles, arriving at the dorsal part of the nasal septum. Many branches are distributed to the nasal area.

The maxillary nerve of the trigeminal has many branches, some to the region of the temporal plexus (p. 20), a branch above the eye to the nasal region, and a branch below to palatine and maxillary regions. The third branch of the trigeminal, the mandibular nerve, innervates many muscles and glands of the jaws and face and carries afferent fibers. (See Cords, 1904; Lakjer, 1926; Starck and Barnikol, 1954, for details).

N. abducens (VI) arises from the floor of the medulla, near the mid-line between the origins of the right and left trigeminals, and innervates the posterior rectus, the quadratus, and the pyramidalis muscles. The n. facialis (VII) also arises from the floor of the medulla beneath the flocculus. It extends a short distance to the dorsal margin of the ear where it divides into its two main branches, at which point is a small geniculate ganglion. An anastomosing network is present above the ear from which an anastomotic branch extends to the semilunar ganglion. We are uncertain of the identification of the chorda tympani nerve; our dissections did not agree in all details with those of Cords (1904) and Yntema (1944). Smith (1941) failed to find any branch joining the fifth and seventh nerves in the turkey.

We were unable to obtain a good dissection of the n. acustica (VIII) and in Fig. 1.7 it is shown as a short stump. The nerve arises from the side of the medulla dorsal to the origin of the seventh nerve. Cords (1904) observed a ramus anterior

and ramus posterior; the former sending branches to utricle, lateral and anterior ampullae, and the latter, to the posterior ampulla, sacculus, and cochlea.

N. glossopharyngeus (IX), n. vagus (X), and n. accessorius (XI) arise as a group of rootlets from the side of the medulla. The glossopharyngeal emerges from the anterior edge of the superior ganglion of the vagus. The accessory nerve is embedded on the opposite side of the same ganglion. The ninth nerve parallels the vagus caudally and ventrally. Beneath the hyoid there is a conspicuous anastomosis, immediately proximal to which is the inferior (r. petrosal) ganglion of the ninth nerve. About midway between the origin of the ninth nerve and its ganglion is the superior cervical sympathetic ganglion, with branches forward to the facial nerve, and ventrally to form a plexus around the carotid artery. It also sends an anastomosis to the hypoglossal nerve and presumably continues within the network between the twelfth cranial and first cervical nerves, to contribute to the sympathetic trunks on each side of the spinal cord.

The distribution of the vagus along the neck and to the visceral organs has been described by Watanabe (1960) in the fowl and Malinovsky (1962, 1963) in the pigeon. In the region of the parathyroid glands there is located the nodose ganglion (Fig. 1.17). The loops of the recurrent laryngeal nerves include the pulmonary artery on the right but not on the left.

The accessory nerve has been variously described. The arrangement shown in Fig. 1.7 agrees with that indicated by Watanabe (1960). The n. hypoglossus (XII) arises from the motor area of the medulla by two roots (Cords, 1904; and illustrated in Hughes, 1934–35) and gives branches to larynx, trachea, tongue, and hyoid in addition to anastomoses with adjoining nerves. Smith (1941) states that in the turkey, the hypoglossal is fused with a branch of the glossopharyngeal nerve.

The first spinal nerve emerges between the skull and atlas (Huber, 1936; Goller,

1962) and thus each succeeding spinal nerve issues from the vertebral canal through the intervertebral foramen. Each spinal nerve lies anterior to its same numbered vertebra. The first cervical nerve lies within the cranial cavity and emerges through the *foramen magnum*. It innervates most of the neck musculature adjacent to the head. The remaining cervical nerves are small as far as the level of the brachial plexus. This plexus is composed of cervicals 15 through 17 and thoracic 1, a total of 4 nerves. Yasuda (1960) and Goller (1962) show nerves, $C_{13\,16}$, and Howell (1937) shows nerves $C_{14\text{-}17}$, involved in the plexus in the chicken. Variability in plexuses has been carefully studied by Furbringer (1888), Gadow and Selenka (1891), and recently by Baumel (1958).

In the pelvic region the *plexus lumbalis (s. cruralis)* includes the third and fourth lumbar and first sacral nerves Goller (1962) shows 4 nerves in this plexus. The *plexus ischiaticus (s. sacralis)* is composed of a caudal ramus from the first sacral nerve and nerves from sacrals 2 through 5. Goller (1962) shows that 6 spinal nerves are involved. Boas (1933) has illustrated the variability in the lumbosacral plexus for 5 chickens. The *plexus pudendalis* is usually depicted as composed of nerves from the first two of the caudal vertebrae as well as a caudal ramus from the last sacral (Goller [1962] shows 4 roots) but all of the caudal and coccygeal nerves are joined by anastomoses that become concentrated into 4 nerve trunks so that it would be difficult to establish a sharp functional separation from the pudendal plexus and the remainder of the caudal nerves (Boas, 1933). Baumel (personal communication) states that in the pigeon a coccygeal nerve plexus can be distinguished posterior to the pudendalis plexus.

Terminology for the nerves distributed to the wing and leg of the fowl has been reviewed by Buchholz (1959-60). (See also Gadow and Selenka, 1891; Yasuda, 1960-61; Fisher, 1946; Hudson and Lanzillotti, 1955.)

Autonomic Nervous System

Two sets of fibers, acting complementary to one another, form the parasympathetic and the sympathetic components of the autonomic nervous system. Portmann and Stingelin (1961) have given a useful diagram of the bird's autonomic system; the relation of the sympathetic trunk to the cranial and spinal nerves is shown by Huber (1936) for the pigeon. Hammond and Yntema (1947, 1958) and Yntema and Hammond (1945) have given detailed reconstructions of the autonomic system in the chick embryo and in the hatched chick 8 days old. Hsieh (1951) has described in great detail the anatomy of the sympathetic and parasympathetic nervous system of the fowl, tracing the small branches to the various organs of the body. Included is an extensive coverage of muscles, arteries, and veins. A brief summarization is given by Grahame (1955).

The sympathetic trunk begins at the superior cervical ganglion (Fig. 1.7) and extends to the level of the sixth coccygeal vertebra. Hsieh (1951) counted 57 pairs of ganglia. The interganglionic cord divides to pass above and below the transverse processes of those vertebrae bearing ribs. The splitting of the cord is more conspicuous in the anterior end of the rib series than caudally. The cord in the mid-body region (T_1–L_1) gives rise to well developed branches distributed by way of the mesenteries to visceral organs. Hsieh found that communicating rami were absent except in the anterior ganglion and last two cervical ganglia and in the caudal part of the body. He found that usually the ventral ramus of each spinal nerve ran through a notch on the dorsal and lateral faces of its sympathetic ganglion and received sympathetic fibers directly.

Sensory Receptors

The largest sensory end-organs, the Vater-Pacini corpuscles, are present near the follicles of contour feathers and in non-feathered areas (Winkelmann and Myers,

1961). These lamellar structures are very numerous in the dorsal dermal layer of the claw and in the beak, especially of ducks. They are present around the joints and between the tibia and fibula (Schildmacher, 1931), in the hard palate, and in the eyelids. Winkelmann (1960) recommends that the synonyms, Herbst, Rauber, and Leydig corpuscles, be dropped because these are all identical structures.   Schildmacher (1931) has identified the layers of a Vater-Pacini corpuscle from the central nerve outward as inner bulb (s. granular layer), inner lamellar layer, outer lamellar layer, and connective tissue capsule. He has suggested that these corpuscles are vibration receptors.

The Grandry corpuscle is characterized by having 2 or more cells, oval in shape and flattened. Their central surfaces are slightly concave and within this space is a tactile disc that receives the terminal network of the axon. Each of these tactile bodies is supplied by a myelinated nerve. These corpuscles are common in the beak of ducks (Portmann, 1961a).

Taste buds are not concentrated on specialized papillae as in mammals but are distributed as isolated follicles on the base of the tongue and floor of the pharynx (Lindenmaier and Kare, 1959; Moore and Elliott, 1946). Duncan (1960) pointed out that birds have fewer than one hundred taste buds whereas mammals have many thousands. The details of structure are shown by Portmann (1961a) who considers that the chief difference from a mammalian taste bud follicle is a peripheral concentration of small sheath cells, but such a sheath was not seen by Greschik (1917) in an Amazon parrot. Avian taste buds may be composed of a few cells that merge with the epithelial cells or may be distinct groups of cells often associated with ducts of palatine glands (Botezat, 1910).

The olfactory nerves from the posterior concha of the pigeon and chicken are a discrete bundle provided with a connective tissue sheath (Locatelli, 1927) but in vultures, albatrosses, and oilbirds, that are sensitive to dilute odors, there are a multitude of delicate strands beneath the olfactory epithelium (Bang, 1960).

Special Sense Organs

The eyes of birds are large relative to the size of the head, yet without certain structural modifications as discussed below, they would need to be even larger to function as effectively as they do. Cones are much more abundant per unit of retina (outside the fovea) of birds than mammals, and since the ratio of efferent nerve fibers is approximately 1:1 for the cones and rods, the optic nerves of birds are relatively large. Pumphrey (1961a) has pointed out that the visual acuity in the fovea is about the same in birds as in mammals but that birds have a much greater range of accommodation, and because cones are more numerous outside the fovea, birds can maintain an accurate view of a wide field whereas the sharpest field for man is limited to 2.5°.

The fovea of birds lies in an *area centralis*. It may be a circular elevated area surrounding the fovea or it may be a streak across the retina in a horizontal plane. The latter is found mostly in species having an aquatic habitat. The concentration of cones in the area is even greater than in the fovea. A comparative study of the ocular fundus of most orders of birds has been given by Wood (1917).

The pecten in birds is a black vertical fan or comb that overlies the optic nerve. Its shape is variable among different species of birds. In the owl it has the form of a trapezoid; its base is 8 mm. and its free edge 5 mm. long. It carries numerous vessels and is thrown into 5 to 30 folds. Details of structure are given by Seaman and Storm (1963) and Seaman and Himelfarb (1963). It has been suggested that the pecten functions as a screen to reduce the light that would enter both eyes simultaneously and in this way helps to retain monocular vision.

The ear of birds is composed of three

parts, an external auditory canal, a middle ear crossed by a columella, and an inner ear divided into a superior part with semicircular canals and utriculus, and an inferior part composed of sacculus, cochlea, and lagena.

Birds lack an external auricle. The external opening is covered with roarse feathers that probably reduce the noise of air movements across the canal and exclude insects. A tympanum forms the boundary between outer and middle ears. Implanted on its inner surface is the columella, a trumpet-shaped bone. The discshaped foot of the stapes (columella) fills the space of the oval window and adjacent to it is the round window that also is covered by a membrane that retains the endolymph fluid. The oval and round windows respond reciprocally to the vibrations transmitted through the stapes to the oval window. Pressures within the middle ear are equalized through the auditory canal. Air cells in some of the head bones also connect with the middle ear cavity.

The utriculus is a sac-shaped structure into which open the three semicircular canals, the horizontal canal has its ampulla with its sensory crest at the anterior end. Joining it is the ampulla for the anterior canal, which generally is the largest and which caudally unites with one end of the posterior vertical canal. The latter has its ampulla near the sacculus. Within the sacculus are flattened sensory discs, *macula utriculi* and *macula neglecta*; the latter is absent in mammals.

The sacculus, located at a 40° angle inferior to the utriculus, is joined to it by a short duct. From it arises a short endolymphatic duct that penetrates the dura of the brain cavity and terminates as the endolymphatic sac. Arising from the sacculus is a slightly curved finger-shaped structure, the cochlea, which is not coiled as in mammals but has the same three canals, *scala vestibuli*, *scala media*, and *scala tympani*. The tegmental membrane is cellular and is thrown into several folds. The basilar membrane probably functions

in the same way as in mammals but would appear to have a more limited range (see Pumphrey, 1961b). The lagena is a static organ and at its tip is the *macula lagenae* functioning as does the *macula sacculi*. Measurements of length and volume for the inner ear of the chicken have been presented recently by Watabe (1960).

RESPIRATORY SYSTEM

Nose, Pharynx, and Trachea

The nose occupies a triangular space between external nares and the margin of the eye. Between the nose and the integument are the lacrimal sinuses that empty into the nasal cavity through the lateral wall. A septum divides the pair of nasal cavities. The lateral walls of the cavity have three conchae, anterior (squamous), medial (ciliated), and posterior (olfactory). (For the anatomy of the respiratory system of the turkey, see Cover, 1953a, b, c.)

Mucosal glands of the lateral and septal walls are arranged in rows separated by ciliated cells (Bang, 1961). The ciliary currents follow the rows; there is a spiral path across the middle concha, and from the middle meatus the direction of flow is toward the roof of the pharynx. The pattern of ciliary currents on the septum corresponds approximately to that on the lateral wall. When young chickens are deprived of water the mucous flow becomes sluggish and erratic (Bang and Bang, 1961). The mucus on the nonciliated olfactory epithelium is removed by the traction from the ciliary activity that surrounds the olfactory area.

The nasal gland (s. salt gland) is small in the galliformes and lies lengthwise against the roof of the orbital cavity. Functionally it supplements the kidneys by reducing the electrolyte content of body fluids when the level is higher than can be handled by the kidneys. It has a particularly important function in marine birds where the salt load is especially great. In its embryology the gland arises from the nasal cavity. It extends forward under the

maxillary process of the nasal bone and its duct empties into the middle meatus through a narrow slit (Technau, 1936). In marine birds the gland usually lies on the dorsal surface of the frontal bone near its lateral margin as shown by Fänge *et al.* (1958) for the herring gull. The organ is divided into lobes and each of these lobes has secreting tubules arranged around a central canal. The organ is supplied by branches from both internal and external ophthalmic arteries whose capillaries have the radial pattern of the tubules.

Scothorne (1959) determined in the domestic duck that the cytoplasm of the secretory cells was densely packed with mitochondria and that the secretion produced was neither mucoid or serozymogenic. Doyle (1960), using the electron microscope, observed that the secretory cells of the salt gland in the black-backed gull (*Larus marinus*) were packed with narrow canals oriented between base and apex of the cell. A salt load caused these spaces to enlarge.

The palate is in part soft and in part hard. Between each right and left half is a longitudinal slit that provides a passageway from nasal to oral cavity (Fig. 1.10). The anterior part of the pharynx begins between the choana and the common opening for the auditory tubes. The entire base of the tongue is located within the pharynx, whereas the tip lies within the mouth cavity. Behind the base of the tongue is the *rima glottidis* or opening of the upper larynx. An epiglottis is absent in birds. The shape of the upper larynx is maintained by the cricoid and arytenoid cartilages—a thyroid cartilage is absent in birds. The opening leads to a tubular trachea supported by complete cartilage rings. Half of each ring is wide and half narrow. These wide and narrow parts alternate with those of adjacent rings.

Immediately above and below the bifurcation of the trachea is a modified area that form a *syrinx* or lower larynx. There is a pair of external tympanic membranes on the lateral surfaces of the syrinx and a pair of internal tympanic membranes on the medial surfaces of the primary bronchi in the region of the pessulus. The syrinx is composed of 4 groups of skeletal elements, namely the 4 tracheal rings above the syrinx proper, the first 3 bronchial half-rings below the bifurcation, 4 intermediate syringeal cartilages located between the two groups mentioned, and finally a bony pessulus (Myers, 1917). In many species of ducks there is an enlargement of the syrinx in males, the tracheal bulla.

Three pairs of striated muscles support the upper larynx and trachea: (1) the combined thyroglossus and the thyrohyoideus from the dorsal surface of the basilyal to the ventral surface of the cricoid cartilage, (2) the tracheohyoideus that extends as bands along the side of the trachea from the sternal spine to the posterior end of the cricoid cartilage, and (3) the sternotrachealis from the medial surface of the anterolateral spine of the sternum along each side of the trachea to the upper larynx (Myers, 1917).

Lungs and Air Sacs

Air is brought to each lung by a primary bronchus that continues through the length of the lung as an S-shaped tube, the mesobronchus, and ends in an abdominal air sac. Secondary bronchi arise in 4 groups from each mesobronchus, 4 ventromedial, 6 dorsomedial, 6 lateral, and about 20 dorsal. The parabronchi (tertiary bronchi) are in the form of loops and usually join an anterior and a posterior group of secondary bronchi (Juillet, 1912; Locy and Larsell, 1916; King, 1956). Air capillaries pass radially from the lumen of the parabronchus and intermingle with the blood capillaries which unite interlobular pulmonary arteries and veins.

An extensive system of air sacs is peculiar to birds (Fig. 1.8). These are thin-walled outpocketings from the bronchi of the lungs that extend around the visceral organs and into many of the bones. The bones of the skull contain pneumatic cav-
FIG. 1.8 — Latex cast of the lungs and air sacs of a chicken from the left side. The cervical air sac in the neck extends anteriorly as far as the atlas, but only that portion is shown here from the 12th cervical vertebra caudally. C, cervical; diver., diverticulum; L, lumbar; T, thoracic. (From USDA.)

ities but these are not connected to the air sacs. These develop as outgrowths of nasal and middle ear cavities. Six pairs of air sacs arise in the chick embryo from the secondary bronchi and the last pair from the caudal end of each mesobronchus. During development there is a fusion of the second and third pairs both across the mid-line and anteroposteriorly to form the large interclavicular air sac (Locy and Larsell, 1916). This air sac has about three primary chambers and several secondary outpocketings or diverticula; the most extensive is a group of axillary diverticula around the shoulder joint lying between the pectoral and supracoracoid muscles. The humeral diverticulum arises from one of these by a narrow canal to enter the proximal end of this bone through the pneumatic foramen. Other diverticula extend into the keel of the sternum, the clavicles, and coracoids. The interclavicular air sac lies entirely below the esophagus. (See Müller, 1908, for the air sacs of the pigeon.)

The most anterior air sac, the cervical, lies above the esophagus and the main chambers fuse across the median line. Four longitudinal trunks extend forward with many cross connections in and around all of the cervical vertebrae except the first. Diverticula penetrate the anterior thoracic vertebrae also and the vertebral members of the first and second thoracic ribs. (See also King, 1957.)

The anterior and posterior pairs of thoracic air sacs are located ventrally and caudally to the lungs and have no diverticula. The turkey has only one pair of air sacs in the thoracic region (Cover, 1953c; Lucas and Denington, 1961). The abdominals form the largest pair of air sacs and invest the pancreas, duodenum, and the coils of the intestine, the caeca, and gonads and the left abdominal air sac surrounds about half the gizzard. Two diverticula surround the hip joint, but none enter the femur, although they do in some species of birds such as the ring-necked pheasant and the Cooper's hawk. Diverticula from the dor-

sal margin practically surround the kidneys and extend into the foramina of the lumbar and sacral vertebrae as well as inside these vertebrae and the iliac bones. The thoracic vertebrae and all of the coccygeal vertebrae as well as the pygostyle are not pneumatized. It has been claimed that the circulation of air through the abdominal air sac reduces the temperature of the testis by a few degrees but Herin et al. (1960) have shown that this is not the case.

A large part of the abdominal air sac is free from adjacent muscle and body wall tissues and therefore is suitable for histologic study (Fig. 1.9). A healthy membrane is extremely thin yet is composed of three layers, an inner simple squamous, endodermal epithelium, a middle splanchnodermal connective tissue layer, and an outer, mesodermal simple squamous serosal epithelium. The vascular and nerve supplies enter the connective tissue layer from the dorsal and lateral body wall. The ventral wall of the abdominal air sac is avascular. Collagenic and elastic fibers form the framework for the middle layer; reticular tissue is absent except perhaps in the blood vessel walls. The endodermal epithelium may sometimes transform into a simple cuboidal or columnar ciliated epithelium within which develop unicellular mucous glands. It is thought that the

ciliated epithelium develops in response to low grade stimuli.

DIGESTIVE SYSTEM

Oropharynx

The oropharynx extends from the tip of the beak to the laryngeal eminence. The junction between the embryonic mouth cavity and visceral arches has been selected as the boundary between mouth and pharynx. This boundary, that has been indicated by dotted lines in Fig. 1.10, cuts across the tongue at the level of the paraglossobasihyal joint. On the roof, the corresponding boundary lies between internal choana and auditory tubes. From these points the lines extend to the angles of the jaws.

The epidermis of the beak has produced a keratinized corneum, which is rigid in most birds but is soft in anserines. The mid-dorsal line of the upper beak is the culmen; the cutting edge, the tomium; and the line of fusion of the two halves of the lower jaw, the gonys. The upper beak extends backward around the external nasal opening and along the maxilla, producing a nasal notch between these processes. About midway along the length of the jaws is located the caudal margin of the gape, the soft tissues of which form the rictus.

Heidrich (1908) describes for the chicken

5 transverse rows of palatine papillae (also shown by Calhoun, 1954) in the roof of the mouth, the last row of which is the largest. In addition, numerous smaller hard tubercles are present between the rows. At the anterior end and along the margins of the mouth are a medial and a pair of longitudinal ridges.

The oropharyngeal glands are small and number at least one hundred. Some of these are illustrated by Heidrich (1908) and Fahrenholz (1937). Calhoun (1954) has followed the classification of Schauder (1923) which is summarized as follows:

1. Glands on the floor of the oral cavity.
   a. Anterior submaxillary.
   b. Posterior submaxillary.
2. Gland in the angle of the mouth (rictus).
   a. Angular oral gland.
3. Glands of the tongue.
   a. Anterior lingual.
   b. Posterior lingual.
4. Glands of the roof of the mouth.
   a. Maxillary gland (Heidrich, 1908).
   b. Medial and lateral palatine glands.
   c. Sphenopterygoid.
5. Glands of the pharyngeal canal.
   a. Crico-arytaenoideae.

All of the glands are compound tubular and produce only mucus.

Esophagus

The esophagus extends down the right side of the neck, enters the thoracic inlet, and follows the mid-line above the trachea to the proventriculus. Many large compound tubular glands empty into the lumen of the esophagus especially in its upper part, and numerous lymphoid follicles are present in its walls. The crop arises as a diverticulum from the esophagus and is positioned lateral to this tube immediately in front of the thoracic inlet. The greater curvature is large when the crop is filled. The relatively smooth mucosa characteristic of the esophagus extends through that portion of the crop forming the lesser curvature. In most birds the crop is a vessel that only stores food temporarily but in pigeons and doves it has the additional function of secreting "crop milk" used in feeding the young.

Stomach

The stomach of birds has two parts, proventriculus (s. glandular stomach) and gizzard (s. muscular stomach). The former is a highly glandular, spindle-shaped organ constricted slightly at its cephalic and caudal ends (Figs. 1.10, 1.11A,B). The mucosa is thrown into plicae and contains many tubular glands (Calhoun, 1954). The surface is dotted with crater-shaped elevations that are the openings for the deep proventricular glands (Fig. 1.11B). The plicae are covered with a simple columnar epithelium that contains goblet cells. The numerous deep proventricular glands are arranged radially around the cavity of the glandular stomach. These glands are compound tubular and the terminal secretory parts empty into a large common cavity within each lobule.

In galliform birds the gizzard is particularly well developed; a comparative study has been presented by Pernkopf (1937). The translocation of the pyloric exit adjacent to the isthmus of the stomach is found in many vertebrates; this produces a short lesser curvature in the chicken and the entire periphery of the muscular stomach becomes the greater curvature. The mantle of muscles on the two faces of the gizzard has a radial arrangement. These lateral muscles (mm. laterales) are united in the center to the central tendon (s. facies lata tendina, tendinous aponeurosis), and along the dorsal and ventral edges of the greater curvature are the semiannular faces. The muscles form two layers, an inner and an outer (Fig. 1.12). Caudal to the isthmus is an intermediate part and at the opposite pole is a thinwalled, caudal sac. The walls of both these are supported by intermediate muscles (mm. intermedia).

In the chicken there is no distinct endpiece at the exit from the gizzard as in

many birds, nor a constriction between end-piece and duodenum called the pylorus. Calhoun (1954) found Brünner's glands (characteristic of the transition between pyloric stomach and duodenum in mammals) in the intestine adjacent to the gizzard. Rosenberg (1931) did not find such glands in the turkey.
Calhoun (1954) and Pernkopf and Lehner (1937) have noted the loss of the *muscularis mucosa* beneath the cuticle of the gizzard. A few fibers noted in our preparation are shown in Fig. 1.12; therefore the *tunica propria* is around the glands and immediately below them, and *the submucosa is adjacent to the lamina muscularis.*

The thick cuticular lining of the gizzard
A

B

is an avian characteristic. Its histologic structure has been analyzed by Eglitis and Knouff (1962). The simple tubular glands of the mucosa secrete within their lumina stiff vertical rods that are maintained intact to the free surface of the cuticle; the epithelial surface as well as the gland crypts secrete a less rigid matrix that surrounds the rods and forms horizontal striae or lamellae. Incorporated within this matrix are desquamated cells.

Intestine and Caeco

The intestine is divided into duodenum, small intestine, and rectum. At the junction of the latter two parts arises a pair of caeca. Gadow (1879, 1889), Mitchell (1901), and Beddard (1911) have applied the coiling of the intestine to taxonomic problems; the coiling in the chicken is one of the most simple among the birds.

The duodenum with its descending and ascending limbs encloses the dorsal and ventral lobes of the pancreas. The pancreas is held between the two layers of the mesoduodenal omentum (Fig. 1.10). The microscopic structure of the turkey duodenum (Rosenberg, 1941) is representative of the galliforms; the villi are flattened plates and are arranged in a herringbone pattern (Fig. 1.11C). The pattern varies in different parts of the digestive tract and

in different species of birds (Müller, 1922). The phylogeny of folds and various types of villi is discussed by Clara (1927). The epithelium is simple columnar and dips into secretory crypts; the supporting tissue forms the *tunica propria* and its peripheral boundary is the *muscularis mucosa*. The submucosa is poorly developed and the muscular stratum is composed of an inner circular layer, a wide circular but slightly oblique layer and an outer longitudinal layer against a subserosa, covered by a simple squamous serous membrane. Calhoun (1954) has described the variations of this pattern for different parts of the digestive tract of the chicken, and Malewitz and Calhoun (1958) for the turkey.

The small intestine, suspended by the dorsal mesentery, pivots around a single point of attachment, at which point the intestine penetrates the mesentery in a dorsal direction. From the straight portion of the lower intestine and rectum arises a pair of caeca; these extend forward, curve to the right and turn caudally where they terminate as closed pouches.

The caeca have diverse forms among species of birds; they are moderately long in the chicken. In pigeons, hawks, eagles, vultures, and parrots as well as some passerines, caeca are rudimentary or absent (Gadow and Selenka, 1891). All of the in-

testine between the caecal junction and the cloaca constitutes the rectum.

Cloaca

The cloaca has three chambers: (1) the coprodeum (fecal chamber) that receives the rectum, (2) the urodeum (urogenital chamber) that receives openings from the ureters and the male or female reproduc-tive ducts, and (3) the proctodeum (vesti-bule) into which empties the duct from the cloacal bursa (s. bursa of Fabricius). There are four folds separating the com-partments (Fig. 1.13): (1) a slight thicken-ing of the wall between the rectum and coprodeum, (2) a well-developed membrane between coprodeum and urodeum, (3) a fleshy membrane between urodeum and

proctodeum, and (4) a membrane at the caudal end of the proctodeum that under conditions of inactivity is folded transversely so that the dorsal and ventral halves face each other. A description of the male accessory organs is given on page 42.

Liver and Pancreas

The liver is a bilobed structure lying ventrally to the posthepatic membrane (s. transverse membrane) and is located within a closed hepatic cavity (Beddard, 1896, 1898; Butler, 1889). The lobes are separated by a ventral mesentery. The right lobe is the larger and the left is partially divided. The shape and variability of these lobes have been analyzed by Lucas and Denington (1956). On the dorsal surface both lobes have central divisions (Fig. 1.11A).

Most species of birds have a gallbladder but it is absent in the hummingbirds and in some genera of pigeons, parrots, cuckoos, and woodpeckers (Van Tyne and Berger, 1959). In the chicken there are two bile ducts, the hepatic arising directly from the liver, and the cystic arising from the gallbladder. Their point of entrance marks the separation between the duo-

denum and the small intestine.

The elongated pancreas in the chicken occupies the duodenal loop. The pancreas in the embryo develops from 3 endodermal buds to form a dorsal lobe and a right and left ventral lobe (Hamilton, 1952; Romanoff, 1960). The ducts and lobes shift position during development; the ventral ducts come to lie close to the hepatic ducts and the dorsal duct is somewhat removed. Three ducts from the pancreatic lobes to the duodenum are shown in Fig. 1.11A. According to Romanoff (1960), the right ventral pancreas fuses with the dorsal pancreas and the left fuses with the right ventral pancreas and ultimately with the dorsal lobe. Dorsal and ventral as labelled in Figs. 1.10 and 1.11A and B refer to their position in the duodenal loop, rather than to their embryonic origin.

The splenic lobe is a continuation of the dorsal lobe and usually lies across the surface of the spleen. The cross-sectional area of the pancreas is greatest toward the distal end (Lucas et al., 1954). The pancreatic islets contain either alpha or beta cells in conjunction with delta cells. Alpha islets are largest and are most abundant in the splenic lobe. Intranuclear inclusions were

found in some beta islets of nearly all chickens examined (Lucas, 1947). Well-illustrated accounts of the avian pancreas have been given by Clara (1921) and Nagelschmidt (1939).

Cloacal Bursa

The cloacal bursa is an ovoid, hollow organ that has a duct leading to the dorsal part of the proctodeum (Fig. 1.13). The shape is variable in different species of birds (Dominic, 1959–60) but in general varies from tubular to piriform. In the chicken, the inner surface is thrown into 11 to 13 primary plicae and 6 or 7 secondary plicae. The lining of the cavity is a simple columnar or pseudostratified epithelium derived from the endoderm. Below this is the *tunica propria* that contains numerous lymphoid follicles. Beyond the follicles are a muscularis layer and a connective tissue covering. Whether the lymphocytes of the *tunica propria* are derived solely from the mesenchyme or in part from the epithelial buds that form the medulla of the follicle has been a controversial question (Ackerman and Knouff, 1959, Ackerman, 1962). It is generally agreed that the epithelial buds produce the reticulum of the medulla and that the cortex is derived from mesenchyme (Boyden, 1922).

EXCRETORY SYSTEM

The excretory organs of the hatched bird are the metanephric kidneys, ureters, and the urodeal portion of the cloaca (Figs. 1.14, 1.15, and 1.16) and their function is supplemented by the nasal gland (p. 28). The kidneys are located caudal to the lungs and extend from the space between the last thoracic and the first lumbar ribs to approximately the level of the last vertebra of the synsacrum. The posterior end of each kidney partially fills the renal fossa, the remainder of the space being occupied by adipose tissue and the sacral diverticulum of the abdominal air sac. The avian kidney has a retroperitoneal location as in mammals but the membrane

covering it in birds is more complex because the dorsal wall of the abdominal air sac has fused with the peritoneum. The fusion extends from the ventral surface of the deferent duct to the middle of the lateral body wall. The remainder of the abdominal air sac is free and is separated from the peritoneum.

The kidney is divided into 3 lobes; the constriction between anterior and middle lobes on the ventral side of the organ is made by the external iliac (s. crural) vein and dorsally by the external iliac artery. The constriction between middle and posterior lobes is produced by the external ischiatic artery (Figs. 1.14 and 1.15).

The ureter emerges from the medial, ventral surface of the middle lobe, just anterior to the ischiatic artery. The duct within the kidney extends close and parallel to the medial margin (Fig. 1.14). It receives numerous branches throughout its length from all of the kidney lobes. The duct passes dorsal to the external iliac vein and ventral to the external ischiatic artery. The ureter runs along the medial edge of the deferent duct in the male and has an equivalent position in relation to the oviduct in the female (Fig. 1.16). Within the kidney parenchyma the ureter subdivides into collecting ducts. These in turn receive urinary fluids from the terminal end of each nephron by connecting tubules. The extrarenal ureter has a muscular wall and elimination of fluids and uric acid crystals is by peristaltic contractions toward the cloaca (Gibbs, 1929).

The nephron of reptiles and birds has glomeruli that are small in size and in birds contain but few capillary tufts. Marshall and Smith (1930) described a central cell mass which Pak Poy and Robertson (1957) in their electron microscopy analysis concluded were cells of the adventitia of the glomerular capillaries and functioned to support these capillaries. Marshall (1934) estimated the number of glomeruli in the kidneys of a fowl of 2,500 grams body weight to be about 814,000 with an average glomerular diameter of 75 microns. In a
FIG. 1.16 — Ventral view of the female urogenital system of the chicken. a., artery; v., vein. (From USDA.)

2,400 gram rabbit, 414,000 glomeruli were estimated for both kidneys and the average diameter was 142 microns. Marshall and Smith (1930) regard the small glomerulus and central cell mass as part of a phylogenetic degeneration process in the avian kidney.

Immediately distal to the glomerulus is a short neck; this is not ciliated in birds and mammals as it is in lower vertebrates.

Following this is the proximal convoluted tubule which has the form of the letter N, as shown by Huber (1917), most of which lies in the cortical portion of the kidney but some of it may extend into the medullary area. A constricted tube lies between the proximal and convoluted tubules. This may be short as in reptiles or long and narrow as in Henle's loop of mammals. Marshall (1934) has given a

Female—Ovary

Normally in the female reproductive system of most birds, only the left ovary is functional; the right regresses during development but for the period soon after hatching it retains the potentiality of development into a testis that may contain sperm or into a functional ovary. Both right and left ovaries are commonly present and functional in hawks and owls. The left ovary is firmly attached by a short mesovarium near the mid-line lateral to the dorsal mesentery. The oviduct is suspended dorsally by the mesosalpinx; ventrally by the mesometrium; the latter is not attached to the body wall but its free border carries many muscular bundles and connective tissue ligaments (Fig. 1.16). The ovary has a cortex and a medulla; the former is composed of a germinal epithelium and an underlying stroma in which layer the follicles develop. The medulla bears the major vessels of the mesovarium.

The ovary, located at the anterior ends of the kidneys, is in the recently hatched chick a flat irregularly shaped gray body with a granular surface. The surface character is due to the presence of innumerable primary oocytes, of which only relatively few will reach maturity and be ovulated. The germinal epithelium lies upon a dense connective tissue layer, the *tunica albuginea*. Beneath this layer lies the stroma of the cortex. The ovary of the laying hen is a large body from the surface of which project follicles in all stages of yolk accumulation. The quiescent follicles in the cortex give to the surface a granular texture. The follicles during development become large and pendulous, the stalks of which carry their vascular supplies. Isolated interstitial cells are present in the stroma, the cytoplasm of which is granular.

During the embryonic development of the ovary a group of germinal epithelial cells invaginates and one of the group forms the ovum, the remainder arrange themselves around the young ovum and form a single layer of "nurse cells" that constitute the *membrana granulosa*. It is these cells in mammals that produce the *corona radiata* but they are not present in the avian egg at the time of ovulation. A double-layered vitelline membrane is produced between the yolk and the *membrana granulosa*.

The germinal disc at the surface of the growing ovum contains the egg nucleus surrounded by a small amount of cytoplasm that merges into the surrounding yolk spheres. The yolk is of two types, white and yellow. The white yolk at the center of the ovum extends to the area beneath the blastodisc and extends laterally as thin concentric spherical laminae separating the wider laminae of yellow yolk.

As the ovum increases in size the adjacent connective tissues of the stroma become organized into the follicular theca of which, in the older stages, a *theca interna* and *externa* may be distinguished. The tissues of the latter merge into the less compact connective tissue of the general stroma. In the internal theca as well as in the stroma are groups of luteal cells.

Bradley and Grahame (1960) have classified ovarian follicles into 5 phases:

1. Primary follicles.
2. Growing follicles.
3. Mature follicles.
4. Discharged follicles.
5. Atretic follicles.

During the process of growth, the theca becomes highly vascularized, particularly in regard to an extensive venous network. On the surface of the follicle opposite the stalk, a slit-shaped area, called the *stigma*, is not as well vascularized as the adjacent area (Nalbandov and James, 1949). The ovum leaves the follicle through a break in the stigma. This produces the "discharged follicle." The thecal cells proliferate. Later the whole structure de-

hypophysis is situated ventrally or rostro-ventrally to the neurohypophysis; it consists of a *pars distalis* and a *pars tuberalis*, and does not have a *pars intermedia*. Within the *pars distalis*, glandular cells are arranged in anastomosing cords and lamellae that are wrapped in a delicate double-layered membrane. A dense plexus of wide blood sinusoids surrounds and partly separates the cords. The several types of cells which make up the cords are distinguished and named according to their reactions to stains (Fayez and Rappay, 1961a and b; Ezrin, 1963). In many birds the *pars distalis* can be divided into cephalic and caudal regions on the basis of the distribution of acidophils (alpha cells) (Rahn and Painter, 1911; Payne, 1942). The boundary between these zones extends from the base of the *pars tuberalis* to the former site of attachment to the diencephalon. Other structures that have been found in the *pars distalis* at various degrees of frequency include pigment granules, colloid-filled cysts, hyperplastic epithelial tissue, and nodules of lymphoid tissue (Payne, 1942; Oboussier, 1948; Payne and Breneman, 1952).

The *pars tuberalis* is a thin layer of cells that forms a collar around the infundibulum and extends forward on the ventral surface of the diencephalon to the region of the optic chiasma. Its histology resembles that of the *pars distalis* except that most of the cells are chromophobes.

A sheath of fibrous connective tissue separates the anterior and the posterior lobes of the pituitary. The latter has two parts, the neural lobe (lobus nervosus or infundibular process) and the infundibulum (neural stalk). The neural lobe is usually a heart shaped or arrow-shaped body, pointed caudally or ventrocaudally, and situated above the caudal region of the *pars distalis*. The infundibulum has hitherto included the infundibular stem and the median eminence, but recent workers tend to consider the eminence as part of the hypothalamus A tubular projection of the diencephalic wall, the stem, connects the neural lobe to the *pars distalis*. Together with the *pars tuberalis* it is sometimes referred to as the hypophysial stalk. The neural lobe and the infundibular stem have a lumen which is continuous with the third ventricle of the brain; in many chickens it is so extensive that the neurohypophysis is entirely hollow (Oboussier, 1948). The median eminence *(eminentia mediana)* is the portion of the ventral or rostroventral wall of the diencephalon between the infundibular stem and the optic chiasma. Anatomically and functionally it may belong to the hypothalamus more than to the pituitary.

The lumen of the neurohypophysis is lined with a single layer of ependymal cells. Outside this is a thick fibrous layer of unmyelinated nerve fibers and several forms of pituicytes (modified glial cells). Beyond this is a palisade layer containing other types of pituicytes, neurosecretory axons, other elements, and masses of neurosecretory granules. This layer is thick in the median eminence but poorly developed in the infundibular stem (Payne, 1959; Kobayashi *et al.*, 1961; Oota and Kobayashi, 1963).

All arteries to the pituitary are branches of the internal carotids, arising from an intercarotid anastomosis. Blood from either the infundibular or the inferior hypophysial arteries enters the neural lobe by way of a superficial plexus and drains directly into the cavernous sinus (dural sinus) in the sella turcica below. A separate net, the primary plexus, on the surface of the median eminence, receives blood from either the infundibular or the superior hypophysial arteries. As in other vertebrates, hypophysio-portal vessels along the *pars tuberalis* carry the blood from the primary plexus to an extensive secondary plexus in the *pars distalis*. Efferent veins lead from here to the cavernous sinus, where blood from the pituitary meets that from the orbit and the forebrain. Blood leaves the sinus by veins which emerge from the skull through the canal for the carotid arteries, just anterior to the external audi-

tory meatus. These veins join the posterior cephalic veins, which in turn join the jugular vein (Neugebauer, 1845).

The pituitary gland is innervated by a hypophysial tract (hypothalamico-hypophysial fasciculus) which arises mostly from neurosecretory nuclei in the hypothalamus. The two component tracts pass along the hypophysial stalk and terminate, one in the median eminence and the other in the neural lobe (Drager, 1945; Green, 1951; Kobayashi *et al.*, 1961). A few fibers go on to the glandular cells of the *pars tuberalis* but none enter the *pars distalis*. The entire gland is said to be innervated by a plexus of the peripheral autonomic nervous system, and the *pars distalis* is further said to contain a very dense secreto-motor end-plexus (Metuzals, 1956).

Most of the pituitary hormones are secreted by the *pars distalis*. Production of adrenocorticotropic hormone (ACTH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH) is regulated by neurohumors that are transported from the hypothalamus by the portal circulation. ACTH and the thyroid-stimulating hormone (TSH) were thought to come from acidophils (Höhn, 1961), but recent findings in mammals indicate types of basophils (beta-1 and beta-2 cells) as the origin (Ezrin, 1963). FSH and LH are produced by two other types of basophils (delta-1 and delta-2 cells) (Fayez and Rappay, 1961a, b; Ezrin, 1963). Prolactin and possibly a growth hormone are produced by two other types of acidophils. Intermedin, which is secreted by the *pars intermedia* of the adenohypophysis in other vertebrates, is formed in the *pars distalis* in birds.

The neurohypophysial hormones of birds are oxytocin and arginine vasotocin; the existence of vasopressin is currently uncertain (Munsick *et al.*, 1960). As in mammals, they are produced in the hypothalamic nuclei, transported in granules along the neurosecretory axons of the hypophysial tract, and stored in the neuro-

hypophysis (Farner and Oksche, 1962). It is no longer believed that additional secretions are produced in the neurohypophysis itself (cf. Payne, 1959).

Adrenal Glands

These glands are paired bodies situated beneath and medially to the anterior lobes of the kidneys, above the gonads, and behind the lungs (Fig. 1.14). They are commonly ovoid, curved, or triangular, but their shape is highly variable among species and individuals and may be polyhedral or flattened and irregular. The glands are cream, yellow, or orange in most species, but they may be white, grey, pink, or brown; color may depend on the lipid content. A gap of variable width usually separates the bodies though in rare cases they are united (Hartman and Albertin, 1951).

The following account of adrenal histology is based on the work of Müller (1929), Knouff and Hartman (1951), and Sinha *et al.* (1959). Each gland is enclosed in a double-layered fibrous capsule which also includes blood vessels, lymph vessels, nerve ganglia, and extrinsic sex ducts. The parenchyma is composed of interrenal (cortical) and chromaffin (medullary) tissues, but these are intermingled rather than zonated as in mammals. The two tissues vary widely in arrangement and relative amount among species of birds (Hartman *et al.*, 1917). They are present in approximately equal volume in White Leghorn chickens, but even here there are variations between sexes and among lines (Oakberg, 1951).

The interrenal cells form cords that wind inward from the periphery of the gland. Each strand is built of radially arranged spherical or cylindrical cells, with a foamy cytoplasm and a deeply staining nucleus near the axis of the cord. Mitochondria, several kinds of lipid droplets (Fayez and Rappay, 1961a, b), and other inclusions are distributed in the cytoplasm. The amounts of lipids and mitochondria are inversely related to each other, and de-

pend on the functional state of the gland (Morita et al., 1961).

The chromaffin tissue takes the form of strands or masses that are sometimes connected by bridges. These cells are irregularly arranged except at the periphery of the gland. They are large and polyhedral, with intensely basophilic granular cytoplasm and vacuolated nuclei. Patches of chromaffin tissue may occur in the capsule of the gland and, as paraganglia, elsewhere in the body. The interrenal and chromaffin tissues are separated by a delicate capillary plexus and a few fibroblasts. Blood from the internal spermatic arteries reaches each gland through a suprarenal artery and branches of the cranial superior renal artery. These vessels send arterioles into the pericapsular sheath, to the plexus, and to central venous sinuses. Large capsular veins collect the blood from the central and the peripheral sinuses, and return it by way of short suprarenal veins to the inferior vena cava.

Several large sympathetic nerves supply ganglia and a rich plexus in the capsule, from whence fibers penetrate the parenchyma to the chromaffin masses. Most of the fibers are myelinated.

The avian adrenal hormones are similar to those of mammals but they are not as well known. The interrenal tissue secretes three main kinds of hormones: mineralocorticoids (e.g., aldosterone), gonadoids (e.g., estrogens and androgens), and glucocorticoids (e.g., cortisone, hydrocortisone, and corticosterone) (de Roos, 1961). The mineralocorticoids regulate the resorption of sodium and potassium from the blood in the kidneys. The gonadoids seem to play a role in the endocrine and spermatogenetic activity of the testes. They may have a masculinizing effect on chickens under abnormal conditions, but such a function is not yet known in normal birds. The glucocorticoids help to control blood sugar and the deposition of glycogen in the liver. The production and action of the interrenal secretions are regulated by the adrenocorticotropic hormone of the pitui-

tary, but the size of the adrenals is not controlled by this hormone as rigidly in birds as in mammals (Zarrow et al., 1962).

The chromaffin tissue secretes adrenalin and noradrenalin in a proportion that varies widely among birds. Noradrenalin accounts for 50 to 60 per cent of the total secretion in the domestic pigeon and 70 to 80 per cent in the fowl (Ghosh, 1962). Both hormones take effect rapidly though briefly, mobilizing body functions to meet stress.

Thyroid Glands

These are a pair of dark red, ovoid bodies on the ventro-lateral surfaces of the neck, just anterior to the first cervical ribs (Fig. 1.17). They lie posterior or deep to the last lobe of the thymus and anterior to the parathyroid glands. The avian thyroids, unlike the mammalian, do not touch the trachea and are not joined by an isthmus. Their size is highly variable, depending on many factors (Ringer, in press).

Each gland is a mass of round to oval follicles within a capsule of fibrous connective tissue. The follicles are lined with a single layer of endodermal epithelial cells on a poorly defined basement membrane. The cells vary in height from columnar to squamous, depending on age, location, and state of activity (Payne, 1957; Yamamoto, 1960). Their nuclei are round or oval, and the cytoplasm stains faintly basophilic and contains many tiny vacuoles. Within each follicle is a homogeneous colloid containing thyroglobulin (protein-bound thyroxine), its quantity varying with the activity of the gland. Cells that appear identical to those of the parathyroid gland occur between the follicles usually in thin septa but occasionally in masses.

Blood from the common carotid arteries reaches the glands by way of the ascending esophageal arteries and their branches, the cranial and caudal thyroid arteries. These supply dense networks of capillaries around the follicles. A sphincter apparatus of endothelium and circular smooth

muscle fibers is sometimes present at the bifurcations of the arteries (Yamamoto, 1960). Owing to the thinness of the interstitial tissue and the basement membrane, the endothelium of the capillaries is almost in direct contact with the follicular epithelium (Ringer, in press). Thyroid veins return the blood to the jugular veins. The innervation of the avian thyroid is not known, but it may come from the cervical sympathetic ganglion as in mammals.

The thyroid gland releases the hormones thyroxine and triiodothyronine that tend to increase oxidative metabolism (Wentworth and Mellen, 1961). They are necessary for normal growth and development, especially of reproductive characters and functioning (Blivaiss, 1947). The enormous amount of research on the functioning of the thyroid has been recently reviewed by Ringer (in press).

Parathyroid Glands

A pair of parathyroid glands is present on each side of the base of the neck, near the posterior end of the thyroids (Fig. 1.17). In pigeons, the lobes of each pair are separated from each other and from the thyroid, whereas in fowl they are sometimes fused together and even attached to the thyroid. If separated from that gland, the parathyroids lie ventral to the jugular vein and dorsal to the common carotid artery. They are spherical to elongate, yellowish-pink or yellowish-white bodies, usually much smaller than the thyroid but sometimes almost half its size (Forsyth, 1908). The anterior parathyroid is usually the larger, and the glands are slightly larger in females than in males.

Each body is enclosed in a capsule of thin connective tissue which is continuous with the tunica externa of the carotid artery. The glands are masses of anastomosing cords supported by delicate strands of connective tissue which are connected to the capsule. Such structure resembles that of the thyroid except that the cords are thicker and there are no vesicles. The cords are composed of closely packed,

columnar epithelial cells, surrounded by a basement membrane (Nonidez and Goodale, 1927). Most numerous are cells with an acidophilic cytoplasm and an intensely staining nucleus (Romanoff, 1960). Oxyphil cells, as found in mammals, are absent. Masses of accessory parathyroid tissue with histologic structure similar to the glands, may be present in the caudal lobe of the thymus, under the capsule of the thyroid, or in the ultimobranchial bodies (Thompson, 1910; Nonidez and Goodale, 1927).

Blood reaches the glands by a short parathyroid artery close behind the caudal thyroid artery, either directly from the common carotid artery or a branch of it: the ascending esophageal artery. The connective tissue stroma supports a rich plexus of capillaries, some of them sinusoidal, with endothelial walls that are nearly in contact with the epithelial cords. Venous blood returns directly to the jugular veins.

The parathyroid hormone (parathormone) plays important roles in regulating the level of calcium in the blood and the renal excretion of phosphorus.

Ultimobranchial (Postbranchial) Bodies

These structures are closely associated with the thymus and the parathyroid glands but they have no known endocrine function. They are situated one on each side of the neck, posterior to the parathyroids, medial to the jugular veins, and anterodorsal to the subclavian artery (Fig. 1.17). The bodies are small, subspherical, or polyhedral, and pinkish (fowl) or yellowish white (pigeon); in some individuals they may be irregular masses or even absent.

They are composed chiefly of compact cords of polyhedral epithelial cells (similar to parathyroid tissue) and spherical or tubular cysts. The latter are lined with squamous or cuboidal epithelium that may be ciliated and are filled with cellular debris or colloid. One or more islets of parathyroid tissue, ensheathed in collagenic tissue, usually occur in the interior of each ultimobranchial body. Nodules of

Digestion

When philosophical speculation began to be replaced by scientific experiment as the basis of biological knowledge, the earliest experiments on digestion were conducted with birds Reamur in 1752 published an account of his studies with kites, which he used because they regurgitate indigestible food residues from the stomach. He fed them various foods in metal tubes with open screened ends and, on recovering them, observed that meat completely disappeared but whole grains resisted digestion. He collected gastric juice by putting sponges in such tubes into the stomach and observed the action of gastric juice on meat *in vitro*. Further experiments using similar methods with carnivorous birds and other animals were conducted by Spallanzini some twenty-five years later. McCollum (1957) in his book, *A History of Nutrition*, describes these fascinating early studies and others in the development of knowledge of digestion. Although digestion has been a very active

field of physiological, biochemical, and nutritional research for many years, concepts have been changed markedly in recent years, and the processes are not yet fully understood. Some of the distinctive aspects of digestion in domestic birds are well recognized, but much of our present understanding of the process in birds is based on the general concepts derived from investigations with other species.

The main function of the digestive system is the reduction of complex food materials by hydrolysis to component water soluble (or water-miscible) units in preparation for absorption and metabolism. This is achieved by a complement of digestive enzymes which catalyze the stepwise hydrolysis of food materials in the controlled environments maintained in the various parts of the system. Viewed in its simplest terms, the digestive tract is a tube into which food is inserted at one end, from which the nutritionally useful por-

TABLE 2.1
THE DIGESTIVE ENZYMES, THEIR LOCATION AND ACTION

Enzymes	Produced by	Location of Action	Action of Enzyme
Carbohydrate-splitting			
Salivary amylase	Salivary glands	Crop	Split starch to polysaccharide and maltose units by hydrolyzing 1, 4-glucoside bonds within the starch molecule
Pancreatic amylase	Pancreas	Duodenum, small intestine	
Biliary amylase	Liver	Duodenum, small intestine	
Intestinal amylases	Small intestine	Small intestine	
Oligo-1, 6-glucosidase			Split branched-chain polysaccharides at 1,6-glucoside bonds
Maltase			Hydrolyze maltose to glucose
Sucrase			Hydrolyze sucrose to glucose and fructose

Protein-splitting			
Gastric protease (pepsin)	Proventriculus	Gizzard	Hydrolyze proteins at linkages containing an aromatic amino acid
Pancreatic proteases			
Trypsin	Pancreas	Duodenum, small intestine	Hydrolyze proteins at linkages containing base amino acids
Chymotrypsins	Pancreas	Duodenum, small intestine	Hydrolyze proteins at linkages of neutral amino acids
Peptidases			
Carboxypeptidase	Pancreas	Duodenum, small intestine	Hydrolyze peptides to amino acids progressively from free carboxyl end
Aminopeptidases	Small intestine	Small intestine	Hydrolyze peptides to amino acids progressively from free amino end
Dipeptidases	Small intestine	Small intestine	Hydrolyze specific peptides to amino acids
Fat-splitting			
Pancreatic lipase	Pancreas	Duodenum, small intestine	Hydrolyze triglyceride, mainly to monoglyceride and fatty acids
Phosphatidases	Pancreas	Duodenum, small intestine	Hydrolyze phospholipids to glycerol, fatty acids, base and phosphate

tion is absorbed, and the unutilized (indigestible) food components are discharged at the other end. Actually the digestion and absorption of foods is a dynamic and complex process which involves a high level of metabolic activity and turnover by the gut. Although the enzymes which catalyze the hydrolysis of food components are effective in very small amounts, the secretions in which they are contained constitute a large flow. For instance, the diet proteins as they are digested to amino acids are diluted as much as sevenfold by the proteins of the secretions of pancreas and small intestine, which in turn are largely digested and recovered. The total flow of amino acids is very much greater than that

represented by the net amount of dietary protein which is digested and absorbed (Nasset and Ju, 1961).

It is estimated that the turnover time of intestinal epithelium in experimental mammals and man is of the order of 1.5–2 days, which meant that the entire lining of the small intestine is completely replaced in this short time. Another evidence of the dynamic nature of the over-all process is the fact that for most nutrients an active process of absorption is involved, rather than a simple diffusion of substances across the wall of the absorbing cell of the intestine. Consequently, the rate of absorption is high for substances that are actively transported, and mechanisms thereby exist for selective

tion is absorbed, and the unutilized (indigestible) food components are discharged at the other end. Actually the digestion and absorption of foods is a dynamic and complex process which involves a high level of metabolic activity and turnover by the gut. Although the enzymes which catalyze the hydrolysis of food components are effective in very small amounts, the secretions in which they are contained constitute a large flow. For instance, the diet proteins as they are digested to amino acids are diluted as much as sevenfold by the proteins of the secretions of pancreas and small intestine, which in turn are largely digested and recovered. The total flow of amino acids is very much greater than that

represented by the net amount of dietary protein which is digested and absorbed (Nasset and Ju, 1961).

It is estimated that the turnover time of intestinal epithelium in experimental mammals and man is of the order of 1.5–2 days, which means that the entire lining of the small intestine is completely replaced in this short time. Another evidence of the dynamic state of the overall process is the fact that for most nutrients an active process of absorption is involved, rather than a simple diffusion of substances across the wall of the absorbing cell of the intestine. Consequently, the rate of absorption is high for substances that are actively transported, and mechanisms thereby exist for selective

absorption. The complexity of the reaction mixtures in the gut has other nutritional implications as well, and it is known that the availability of some nutrients, especially minerals, can be markedly influenced by composition of the diet.

Knowledge of the digestive machinery and its functioning in a given species is based on (1) the enzyme apparatus, and the physiological environment in which it functions; (2) the properties of food materials which are processed, including the susceptibility of their components to enzymatic hydrolysis and the action of inhibitory substances which the food may contain; and (3) the total processing capacity of the tract. Each of the aspects will be considered in this discussion of digestion in birds. Limited consideration will be given to anatomical structure and relationships. For more detail the reader is referred to Chapter 1 on anatomy in this volume. Further sources are an extensive discussion by Farner (1960) and an authoritative review and study on microanatomy by Calhoun (1954). Selected general references which reflect current concepts based on modern studies in biochemical and physiological mechanisms of digestion and absorption are grouped in a special section of the references

THE ENZYMATIC MACHINERY OF DIGESTION

The complement of digestive enzymes considered to be present in the digestive system of chickens and other birds is shown in Table 2.1, which summarizes their location and action. The biochemical characteristics of the avian enzymes, to establish their detailed mechanisms of action, are not so well known as the more thoroughly studied mammalian enzymes.

However, the general functioning of the avian digestive system, its efficiency of digestion, the *in vitro* action of the various digestive secretions, and the effects of enzyme inhibitors which have been studied, all indicate that the avian system has the characteristics common to nonruminants generally. In the discussions to follow, particular reference will be made to information known specially to apply to poultry, but most of the material on the action of digestive enzymes has come from investigations with mammals.

The environment in which the digestive enzymes act is controlled physiologically, and is affected little by diet except under rather extreme conditions. The typical pH conditions in the various sections of the tract are shown in Table 2.2. These differ from the typical conditions in mammals by (1) less acid stomach contents, (2) somewhat more acid intestinal contents, and (3) an acid bile.

Carbohydrate Digestion

The main carbohydrate in the diet of birds is starch, supplied by grains or grain by products. The over-all process is indicated in the following equation which depicts the hydrolysis of starch to glucose, the unit compound absorbed into the blood and transported to the cells of the body.

This oversimplified description of the digestion of starch to glucose shows that it proceeds by hydrolysis, and that for every 162 grams of starch hydrolyzed there are produced 180 grams of glucose. There is essentially no change in the gross energy value in this process; although glucose has a lower energy value per gram this is a result simply of the increase in weight on hydrolysis, and the total amount of combustible energy in the equivalent amounts

$$(C_6H_{10}O_5)n \xrightarrow[\text{alpha-amylase}]{.5n \ H_2O} 5nC_{12}H_{22}O_{11} \xrightarrow[\text{maltase}]{.5n \ H_2O} nC_6H_{12}O_6$$

Large intestine	6.3	6.5	6.7	6.6	5.4
Ceca	5.7	5.9	5.9	5.4	—

*Adapted from Farner (1942)

of starch and glucose is virtually the same.

Four kinds of enzymes participate in the stepwise hydrolysis of carbohydrates. The chicken produces saliva which contains amylase (carbohydrate-splitting) activity (Leasure and Link, 1940). The action of this amylase occurs in the crop during any temporary storage of food there. This action probably stops in the gizzard because of the low pH. Further carbohydrate digestion is carried on in the intestine by the amylase of pancreatic juice. Both the salivary and pancreatic amylases are alpha-amylases which attack the starch molecule by hydrolysis of random 1,4-glucoside linkages within the molecule, producing successively smaller polysaccharide units. Starch molecules consisting of straight chain (amylose) polymers have only the 1,4-linkages and can be completely degraded to the disaccharide maltose ($C_{12}H_{22}O_{11}$) by the action of these two amylases. A part of the starch in grains has a branched chain structure termed amylopectin which cannot be completely hydrolyzed by the salivary and pancreatic alpha-amylases. It requires another pancreatic enzyme termed 1,6-oligoglucosidase which specifically hydrolyzes the branching linkages, and allows the further degradation of the starch to maltose. Maltose is hydrolyzed to glucose by an intestinal enzyme called maltase. It is yet uncertain whether this enzyme acts in the intestinal lumen, or whether the final degradation of maltose to glucose takes place in the cells of the intestinal mucosa.

Specific enzymes for the hydrolysis of other disaccharides are also present in the digestive tract. They include sucrase which hydrolyzes sucrose, and lactase which hydrolyzes lactose and has been shown to be present in the crop (Hamilton and Mitchell, 1924).

Since domestic birds are grainiferous animals, it is pertinent to note that grains and other plant materials contain amylases which are active under appropriate conditions of moisture and pH. These enzymes are beta-amylases which differ from the alpha-amylase of animals in that they split maltose units from the ends of starch molecules rather than hydrolyzing interior linkages. Digestion by plant amylase action could occur in the crop or in the intestine.

Protein Digestion

The end products of protein digestion are the amino acids, which are the unit components of the highly complex protein molecules. The degradation is achieved in a stepwise fashion, with the participation of enzymes from gastric juice, pancreatic juice, and the intestinal secretions. From a nutritional standpoint, there is no significant absorption of intact protein molecules or peptides. In making this statement, it is recognized that in very young animals there is absorption of intact proteins or protein subunits from the gut, and that this is an important mechanism for acquisition of antibodies; furthermore, it is recognized that absorption of antigenic amounts of proteins is involved in allergies. From an over-all view of protein nutrition, however, these are of minor magnitude and will not be considered further in this discussion.
The various proteases, as shown in Table 2.1, have a high degree of specificity

absorption. The complexity of the reaction mixtures in the gut has other nutritional implications as well, and it is known that the availability of some nutrients, especially minerals, can be markedly influenced by composition of the diet.

Knowledge of the digestive machinery and its functioning in a given species is based on (1) the enzyme apparatus, and the physiological environment in which it functions; (2) the properties of food materials which are processed, including the susceptibility of their components to enzymatic hydrolysis and the action of inhibitory substances which the food may contain; and (3) the total processing capacity of the tract. Each of the aspects will be considered in this discussion of digestion in birds. Limited consideration will be given to anatomical structure and relationships. For more detail the reader is referred to Chapter 1 on anatomy in this volume. Further sources are an extensive discussion by Farner (1960) and an authoritative review and study on microanatomy by Calhoun (1954). Selected general references which reflect current concepts based on modern studies in biochemical and physiological mechanisms of digestion and absorption are grouped in a special section of the references.

THE ENZYMATIC MACHINERY OF DIGESTION

The complement of digestive enzymes considered to be present in the digestive system of chickens and other birds is shown in Table 2.1, which summarizes their location and action. The biochemical characteristics of the avian enzymes, to establish their detailed mechanisms of action, are not so well known as the more thoroughly studied mammalian enzymes.

However, the general functioning of the avian digestive system, its efficiency of digestion, the *in vitro* action of the various digestive secretions, and the effects of enzyme inhibitors which have been studied, all indicate that the avian system has the characteristics common to nonruminants generally. In the discussions to follow, particular reference will be made to information known specially to apply to poultry, but most of the material on the action of digestive enzymes has come from investigations with mammals.

The environment in which the digestive enzymes act is controlled physiologically, and is affected little by diet except under rather extreme conditions. The typical pH conditions in the various sections of the tract are shown in Table 2.2. These differ from the typical conditions in mammals by (1) less acid stomach contents, (2) somewhat more acid intestinal contents, and (3) an acid bile.

Carbohydrate Digestion

The main carbohydrate in the diet of birds is starch, supplied by grains or grain by-products. The over-all process is indicated in the following equation which depicts the hydrolysis of starch to glucose, the unit compound absorbed into the blood and transported to the cells of the body.

This oversimplified description of the digestion of starch to glucose shows that it proceeds by hydrolysis, and that for every 162 grams of starch hydrolyzed there are produced 180 grams of glucose. There is essentially no change in the gross energy value in this process; although glucose has a lower energy value per gram this is a result simply of the increase in weight on hydrolysis, and the total amount of combustible energy in the equivalent amounts

$$(C_6H_{10}O_5)_n \xrightarrow[\text{alpha amylase}]{.5n\ H_2O} 5nC_{12}H_{22}O_{11} \xrightarrow[\text{maltase}]{.5n\ H_2O} nC_6H_{12}O_6$$

*Adapted from Farner (1942)

of starch and glucose is virtually the same.

Four kinds of enzymes participate in the stepwise hydrolysis of carbohydrates. The chicken produces saliva which contains amylase (carbohydrate-splitting) activity (Leasure and Link, 1940). The action of this amylase occurs in the crop during any temporary storage of food there. This action probably stops in the gizzard because of the low pH. Further carbohydrate digestion is then carried on in the intestine by the amylase of pancreatic juice. Both the salivary and pancreatic amylases are alpha-amylases which attack the starch molecule by hydrolysis of random 1,4-glucoside linkages within the molecule, producing successively smaller polysaccharide units. Starch molecules consisting of straight chain (amylose) polymers can have only the 1,4-linkages and can be completely degraded to the disaccharide maltose ($C_{12}H_{22}O_{11}$) by the action of these two amylases. A part of the starch in grains has a branched chain structure termed amylopectin which cannot be completely hydrolyzed by the salivary and pancreatic alpha-amylases. It requires another pancreatic enzyme termed 1,6-oligoglucosidase which specifically hydrolyzes the branching linkages, and allows the further degradation of the starch to maltose. Maltose is hydrolyzed to glucose by an intestinal enzyme called maltase. It is yet uncertain whether this enzyme acts in the intestinal lumen, or whether the final degradation of maltose to glucose takes place in the cells of the intestinal mucosa.

Specific enzymes for the hydrolysis of other disaccharides are also present in the digestive tract. They include sucrase which hydrolyzes sucrose, and lactase which hydrolyzes lactose and has been shown to be present in the crop (Hamilton and Mitchell, 1924).

Since domestic birds are grainiferous animals, it is pertinent to note that grains and other plant materials contain amylases which are active under appropriate conditions of moisture and pH. These enzymes are beta-amylases which differ from the alpha-amylase of animals in that they split maltose units from the ends of starch molecules rather than hydrolyzing interior linkages. Digestion by plant amylase action could occur in the crop or in the intestine.

Protein Digestion

The end products of protein digestion are the amino acids, which are the unit components of the highly complex protein molecules. The degradation is achieved in a stepwise fashion, with the participation of enzymes from gastric juice, pancreatic juice, and the intestinal secretions. From a nutritional standpoint, there is no significant absorption of intact protein molecules or peptides. In making this statement, it is recognized that in very young animals there is absorption of intact proteins or protein subunits from the gut, and that this is an important mechanism for acquisition of antibodies; furthermore, it is recognized that absorption of antigenic amounts of proteins is involved in allergies. From an over-all view of protein nutrition, however, these are of minor magnitude and will not be considered further in this discussion.

The various proteases, as shown in Table 2.1, have a high degree of specificity

in the kinds of peptide linkages which they hydrolyze. The gastric juice contains the gastric protease (pepsin) and hydrochloric acid. It is secreted by the true stomach (proventriculus) and carries on its action primarily in the gizzard. Its action is to hydrolyze proteins at peptide linkages which involve an aromatic amino acid. The action of gastric juice is followed by the pancreatic proteases, trypsin and chymotrypsins, contained in pancreatic juice which enters the small intestine at the distal end of the duodenum. These enzymes also hydrolyze specific peptide linkages as indicated in Table 2.1. By this time the proteins have been reduced to smaller and more soluble polypeptide fragments. They are hydrolyzed to amino acids by three kinds of enzymes. One, from the pancreas, termed carboxypeptidase, hydrolyzes proteins and peptides progressively from the free acid end of the molecule. Other enzymes classed as aminopeptidases, produced by the tissues of the small intestine, conduct a similar progressive hydrolysis beginning from the end of the molecule with the free amino group. Other specific intestinal enzymes split specific dipeptides.

Fat Digestion

Hydrolysis of fats is catalyzed by the pancreatic lipase (fat-splitting enzyme) in a process which is in some ways more complex than the digestion of either carbohydrates or proteins. The pancreatic and bile secretions establish an intestinal pH of approximately 6 in which environment the bile acids emulsify the dietary fats so that they present a large surface for lipase action. The lipase catalyzes the partial hydrolysis of triglyceride fats, splitting off fatty acids by hydrolyzing the primary (alpha) glyceride ester linkages. The end product of this hydrolysis is mainly fatty acids and the 2-monoglyceride ester, because the pancreatic lipase is specific for the hydrolysis of the terminal (alpha) ester linkages (Mattson and Beck, 1956). However, part of the fat is hydrolyzed only to the diglyceride stage, and a small amount is hydrolyzed completely to fatty acids and glycerol; the complete hydrolysis apparently occurs because the 2-monoglyceride isomerizes to form 1-monoglyceride, which can be attacked by the lipase. The following is a scheme of triglyceride hydrolysis by pancreatic lipase:

The monoglycerides are powerful solu-

Triglyceride

⊦ indicates glycerol molecule)

Diglyceride + fatty acid

2-Monoglyceride + fatty acid

1-Monoglyceride

Glycerol + fatty acid

bilizing substances, with the result that the combination of monoglycerides, diglycerides, bile salts, and fatty acids, together with some undigested triglyceride forms a highly stable fat-in-water unit known as a micelle (Hofmann and Borgstrom, 1962). This is similar to the action of detergents in solubilizing many substances. It is in the micelle form that the fat is absorbed by the intestinal cells. Within the cells there is resynthesis of the components of the mixture into triglyceride fat which is then transported to body cells. There is considerable controversy as to the proportion of the triglyceride fat which is hydrolyzed to the monoglyceride form in digestion. The weight of present evidence supports the view that the hydrolysis of a highly absorbable fat to monoglyceride and fatty acids is essentially complete, and only a small proportion of the fat is absorbed as triglyceride. This is based on the analysis of intestinal contents during digestion *in vivo*, and on experiments using fats labelled with radioisotopes which have shown extensive redistribution of fatty acids in the absorbed fat as compared to the ingested fat. This is also consistent with the finding that unabsorbed fat appears in the feces as fatty acids and soaps, rather than as glycerides.

The Control of Enzyme Secretion

The glands which secrete the enzymes and digestive juices are protected from self-digestion mainly because the enzymes are present in them in inactive forms. In the secretory cells of the pancreas, for instance, the enzymes are contained in small granules known as zymogen granules. The enzymes, which are proteins, require a chemical activation which usually involves either hydrolysis of a particular peptide bond in its structure, or the splitting out of an inactive fragment (polypeptid) of the molecule. The activation of the protein-splitting enzymes is well understood, and can serve to illustrate the principle. The gastric protease, pepsin, is secreted as pepsinogen and is activated by hydrochloric acid which is produced by separate cells. Pepsin also activates pepsinogen and the process is therefore autocatalytic. The pancreatic proteases are secreted in the inactive forms trypsinogen and chymotrypsinogen. An intestinal enzyme, enterokinase, activates trypsinogen to form trypsin, which in turn activates more trypsinogen and also chymotrypsinogen. In addition to confining the inactive enzymes in zymogen granules, the cells are equipped with enzyme inhibitors, the purpose of which is evidently to prevent damage from chance release of active enzymes within the cell.

The secretion of the various digestive juices is controlled in mammals by hormones which are produced by the gut tissues in response to the presence of food. Gastrin is produced by stomach tissue, and causes the secretion of gastric juice. Four hormones are produced by the intestinal tissues. Cholecystokinin causes gallbladder contraction to produce bile flow. Secretin stimulates pancreatic juice flow, causing secretion of juice high in sodium bicarbonate and low in enzyme activity; pancreozymin causes secretion of enzyme-rich pancreatic juice. Enterogastrone acts to inhibit flow of chyme from stomach to intestine, and acts as a rate regulator. It is likely that mechanisms analogous to these regulate digestive secretions in birds as well.

THE ORGANS OF DIGESTION AND ABSORPTION

The special features of the digestive tract of birds are easily distinguished and are related to feeding behavior and digestive efficiency. A brief description of the parts, their general functions, and particular characteristics form this section of the discussion.

Mouth

The mouth is hard surfaced, lacks teeth, and has a relatively sparse supply of salivary glands (Leasure and Link, 1940)

digestive secretions. It has a keratinized lining formed by the underlying glandular layer of the organ. The grinding action of the gizzard is greatest when stones (grit) are present, and insoluble grit can be retained in the gizzard for a very long time. The efficiency of digestion is impaired when diets containing whole grains are fed in the absence of a grinding agent, but there is little effect of grit on digestibility when the diet is composed entirely of ground components (Fritz, 1937). With the commonly used meal (mash) or pelletized diets in commercial meat production, for instance, there is no significant effect of grit on growth rate, food intake, or apparent efficiency of food utilization.

Surgical removal of the gizzard does not impair digestive function or survival so long as a suitably ground ration is fed. Digestibility studies with gizzardectomized birds have shown little impairment in food utilization (Fritz et al., 1936).

Small Intestine

This part of the digestive tract is the main section for food processing and absorption. The proximal part of the small intestine forms the duodenal loop within which is situated the large and well-defined pancreas. Gastric digestion probably continues in the early part of the duodenum until the point is reached at which pancreatic secretions (3 ducts) and bile (2 ducts) enter the gut. These secretions establish an intestinal pH in the range 5.5–6.5 which inhibits the gastric protease but allows effective digestive action of the enzymes of the pancreas and intestine. All three of the major kinds of food components are attacked by the pancreatic secretions as indicated in the summary of digestive enzymes and their action presented in Table 2.1. The main task of carbohydrate hydrolysis is carried on by the pancreatic amylase, and it has been reported that the bile in the chicken also contributes amylase activity. The pancreas also furnishes the only known digestive lipases which function in the bird.

Removal of the pancreas or ligation of the pancreatic ducts causes a profound reduction in the digestion of protein and fat in the chicken. The effect on starch digestion is much less striking, the reduction being to about 70 per cent of normal digestibility. Digestion can be restored essentially to normal levels by the addition to the diet of raw beef pancreas, or presumably pancreatic tissue from other animal sources (Ariyoshi et al., 1964).

The small intestine is lined with finger like projections (villi), the surfaces of which are made up of absorbing cells and mucussecreting (goblet) cells. It has been commonly considered that the secretions of the small intestine (the so called succus entericus) contribute the enzymes which are involved in the terminal hydrolysis of carbohydrates and proteins. On the basis of relatively recent studies, it appears at least equally likely that the hydrolysis of disaccharides and small peptides may take place in the absorbing cells of the intestinal mucosa rather than in the lumen of the intestine. It is the surface cells of the villi which participate in the rapid desquamation and regeneration which makes the gut metabolism so dynamic. It is considered likely that the intestinal enzymes in the lumen of the gut come from the desquamated cells rather than from secretory glands.

Ceca

At the junction of the small and large intestines are two blind pouches which are termed ceca. In the part adjacent to the intestine, villi are present and the general structure is similar to the small intestine. In the midportion villi are less typical and less numerous, while in the typical and less numerous, while in the ceca blind ends villi are not present. The ceca evidently do not produce any digestive secretions. They may be concerned with water absorption, since the cecal contents are generally lower in moisture content than the adjacent parts of the intestine. It has often been stated that the ceca may participate in digestion of cellulose

through the action of microorganisms, but this seems to have little or no nutritional significance. Surgical removal or ligation of the ceca does not interfere with digestive functions of the tract. The size of the ceca and nature of their contents may be markedly affected by diet; in particular, feeding lactose increases the fluidity of the contents and markedly lowers the pH of the ceca.

The significance of the microbial flora of the digestive tract has been studied extensively in recent years since the discovery that feeding small amounts of antibiotics may have nutritional benefits. A favorable effect of microbial fermentation on nutrition has been demonstrated in the case of biotin (Sunde et al., 1950) and vitamin K (Nelson and Norris, 1961), both of which are synthesized by the intestinal flora and are absorbed in nutritionally significant amounts. Removal of the ceca has been shown to improve the nutritional status in respect to these vitamins when a deficient diet is fed, indicating that the flora of the ceca destroy these vitamins or inhibit their synthesis by other organisms. In these cases at least, the effects of cecal microorganisms appear to be negative rather than beneficial. Under normal circumstances, it may be that the cecal flora are essentially innocuous, and that they may constitute a buffer against invasion by more deleterious microorganisms. However, there are no known digestive functions which can be ascribed to the ceca and their removal has no deleterious effect.

Large Intestine

Birds are characterized by a short large intestine. Its structure resembles that of the small intestine and it appears to perform some absorptive functions. Water absorption is known to take place and it is probable that it functions in regulating electrolyte balance. The large intestine communicates with the cloaca, the common excretory organ into which the urinary wastes are delivered. It has been demonstrated by radiographic studies that urine enters the large intestine and that the absorption of water and salts can occur in this region. It is probable that no important digestive and absorptive function with respect to the major organic nutrients occurs in the large intestine, since apparent digestibility is similar in colostomized and intact birds.

ABSORPTION

Absorption in the mouth and crop is limited but significant, as shown by studies in which glucose absorption was demonstrated (Soedarmo et al., 1961). Interestingly, absorption from the crop is evidently selective, because the botulinus toxin was shown to be completely unabsorbed from the ligated crop (Leasure and Folz, 1940). Absorption is mainly the function of the small intestine, which is admirably constructed to perform this function. The lining of the small intestine is covered with long fingerlike projections which are called villi. The villi are lined with absorbing cells, the outer surfaces of which are made up of microscopic fingerlike projections known as microvilli. This complex surface of the intestine provides an effective absorptive area several hundredfold greater than it would be as a simple smooth rylindrical tube. The spaces between the microvilli define the limiting dimensions of particles or micelles which can be absorbed. The structure of the luminal surface of the absorbing cells possesses the mechanisms for active absorption of nutrients. The absorbing cells which form the surface of the villi are in the constant process of growth, desquamation, and renewal which makes up the dynamic turnover of intestinal tissue.

The function of the digestive process is to hydrolyze food components to their unit structures in preparation for absorption by the intestinal cells. For both carbohydrates and amino acids, there is compelling evidence to show that the process of absorption is an active one—not simply a matter of diffusion of the water-soluble compounds across the cell wall into the

intestinal mucosa. The evidence for active transport is based on observations showing that simple sugars differ markedly in the rate at which they are absorbed—for instance, xylose is absorbed by diffusion at a slow rate, while glucose is absorbed comparatively rapidly. Furthermore, galactose, glucose, and fructose, all actively absorbed, differ markedly in rate of absorption. The evidence for amino acids shows that the stereoisomers are absorbed at different rates indicating a selective and active transport for the nutritionally important amino acids. After absorption into the absorbing cells these substances are transferred into the blood stream across the base of the cell.

At the present time, it is not known whether a similar active transport system is involved in the absorption of fats. The significance of the micelle structure as the form of fat absorption seems well established, but a transport mechanism has not been defined.

A micelle size of the order of 50 mμ diameter is necessary in order to penetrate the space between two microvilli, and this is readily achieved under the conditions of the intestine. After absorption, triglyceride fat is resynthesized in the absorbing cell, and the fat droplet is ready for transport. In the mammal, this is mainly in the lymph via the thoracic duct to the jugular vein. In birds, it is not known whether the main path is via the lymphatics or the portal blood.

Different regions of the small intestine apparently are involved in the absorption of various classes of substances. The fats are absorbed in the proximal half of the small intestine. The absorption of various carbohydrates differs as to location. This regional specificity likewise suggests that specific transport mechanisms are involved for all of the important major nutrients.

NUTRITIONAL ASPECTS OF DIGESTION

The digestive tract of the chicken and other domestic birds is relatively short, and the time required for food to pass through the tract is also relatively short. Data illustrating approximate time for food passage are summarized in Table 2.3 (Hillerman *et al.*, 1953). In spite of these seeming disadvantages, the efficiency of digestion and the total capacity for the intake and processing of foods are quite high.

Chickens are typical nonruminants, as illustrated by ability to utilize various reference substances (Table 2.4). Cornstarch, sucrose, and glucose are nearly quantitatively digested and absorbed, while cellulose is completely unutilized. The utilization of these carbohydrates as they exist in natural food materials is consistent with the results obtained when they are fed as the pure substances.

Estimation of the carbohydrate value of a feeding material is frequently made on the basis of chemical analysis for crude

TABLE 2.4

fiber, which determines that portion of the organic matter of the feedstuff which is undissolved by hot acid and hot alkali. This analytical method makes an empirical estimation of the indigestible carbohydrates, including variable amounts of cellulose and hemicelluloses which form the main part of plant cell walls, and lignin which is a cementing substance of plant cell walls. Tables of digestibility of food components frequently indicate a measurable digestibility of the crude fiber fraction of feeding materials, suggesting that these complex carbohydrates are somehow digested and utilized. It is quite clear that there are no animal-produced enzymes which can hydrolyze cellulose or lignin, so that whatever modification or disappearance of these compounds apparently takes place in the digestive tract of a bird is due to the action of plant or microbial enzymes. The nutritional significance of "digestible" crude fiber is therefore open to question, and it is more likely to be due to analytical artifacts than to true utilization. When it is also recognized that the crude fiber determination generally underestimates the total indigestible carbohydrates of the feeding material, it becomes clear that this empirical estimation is of very limited utility in estimating the value of feeds for birds.

Direct determination of starch and sugar content of feedstuffs to estimate their useful carbohydrate content is a promising approach (Carpenter and Clegg, 1956) and may be developed into a more comprehensive system of feed evaluation. All chemical methods are complicated by the fact that the digestibility of a feedstuff may be influenced by the distribution of the indigestible components such as cellulose and lignin. Since these compounds make up the cell walls of plant materials, it is possible that they may protect otherwise digestible components that are "locked" within the cells. This is the basis for the view that crude fiber or indigestible carbohydrates interfere with the utilization of other nutrients, and therefore are an underestimate of the total indigestibles of the diet. The addition of pure cellulose to a diet does not reduce the utilization of other components, but is handled by the bird simply as a diluent.

Extensive investigations of the digestibility of various carbohydrates and crude fiber in natural feedstuffs have been reported by Fraps (1931) and Bolton (1955). Their findings agree with the concept that starches and sugars are highly utilized, and that cellulose and lignin have zero value. The main uncertainties are associated with estimating the utilization of hemicelluloses and pentosans which are of questionable value to the bird. Cellulose has been shown to be unutilized, both by digestion trials (Tasaki and Kibe, 1959) and in metabolizable energy studies (Anderson et al., 1958). Turkeys have been considered to be good "roughage consumers," and it was thought that they might make better use of crude fiber components than other birds. Dymsza and co-workers (1955) found very little apparent utilization of crude fiber in digestion studies with growing turkeys.

As indicated in Table 2.4, the utilization of various isolated proteins is also quite high. Furthermore, the capacity or tolerance for high dietary levels of protein is also high. There is no apparent reduction in protein digestibility when diets containing protein at twice the usual levels or even more are fed. In general, the digestibility of feedstuff proteins from plant and animal sources can be considered to be of the order of 80–85 per cent. However, the proteins classified as keratins, from such sources as hoofs, feathers, and hair, are poorly digested. Also proteins which are subjected to severe heat treatment in processing may show reduced digestibility due to the creation of chemical bonds which are resistant to attack by digestive enzymes. These effects can be detected by in vitro enzyme digestibility (such as with pepsin or trypsin), by solubility in various solutions (such as dilute alkali), or by analysis for specific chemical linkages. One

of the latter which is of particular interest is the estimation of the epsilon-amino group of lysine. In undamaged proteins, this reactive group is in the free uncombined state and can be measured by appropriate reagents; in a heat-damaged protein, this group forms indigestible linkages. A decrease in epsilon-amino lysine indicates both a decrease in the lysine value in the protein and also general damage which interferes with digestion (Carpenter, 1960).

Vegetable oils and such animal fats as lard and the fat of poultry are well utilized by chickens and other domestic birds. Furthermore, the capacity for utilization of fat is very high, and it has been shown experimentally that diets in which most or even all nonprotein calories are derived from fat can be fed successfully (Donaldson et al., 1957; Renner and Elcombe, 1963). This is in interesting contrast to the generally accepted view of only a few years ago that poultry have a very limited capacity to utilize fat. Digestibility (absorbability) data for representative fats are given in Table 2.4 and show virtually quantitative utilization of common vegetable oils and low melting animal fats. Animal fats of high melting point, such as beef tallow, are less well utilized (Renner and Hill, 1960a). Studies of the utilization of fatty acids fed as such have shown that the long chain saturated fatty acids are virtually unutilized; absorbability is higher for shorter chain saturated fatty acids. The unsaturated fatty acids, as oleic acid and linoleic acid, are highly absorbable. The absorbability of a particular fatty acid depends on the composition of the mixture in which it is fed, but in general the utilization of saturated fatty acids fed in the free form is very much less than when they are part of a triglyceride fat. This is consistent with the present concept of digestion and absorption of fats (as discussed in a previous section) in which the formation of micelles through detergent action depends on the presence of monoglycerides. In general, it is found that a

free fatty acid mixture derived from the hydrolysis of a triglyceride fat is less well utilized than the fat from which it was prepared (Renner and Hill, 1961). Recent studies have indicated that oleic acid may have special properties in facilitating the utilization of other fatty acids (Young and Garrett, 1963).

An extensive summary of the scientific literature on digestibility of feedstuffs for poultry has been prepared by Olsson (1950). It is organized according to the conventional analysis scheme for feeding materials and shows the apparent digestibility for crude protein, ether extract (fat), crude fiber, and nitrogen-free extract (carbohydrate). Digestibility studies are difficult to conduct with birds because they excrete the indigestible and urinary wastes together. Surgical alteration (such as colostomy) or chemical separation of the excreta components is necessary. The older data in the literature are particularly subject to the limitations of the methods used. The total nutrient value of the major organic components of feedstuffs can be determined as metabolizable energy (ME) by heat of combustion analysis (bomb calorimetry) using the mixed excreta (Hill et al., 1960). Extensive studies of the ME value of feedstuffs for poultry have been conducted in recent years. The values obtained agree closely with those which can be calculated from well-conducted digestion trials, showing that the total ME of a diet or diet component is the sum of the energy values of its digestible protein, carbohydrate and fat. Representative values for the ME of some common feeding materials are shown in Table 2.5.

INHIBITORY EFFECTS

Deleterious effects on digestion and absorption are associated with certain feedstuffs. Uncooked soybean meal has a marked growth retarding effect on nonruminant animals, including chicks and turkey poults, due to the presence of several growth inhibiting substances. A

part of the effect is due to the so called soybean trypsin inhibitor, a substance which specifically interferes with the action of the digestive enzyme trypsin. The digestibility of unheated soybeans or soybean meal by chickens is lower than for the properly cooked materials, and the inhibitors affect the utilization of both protein and fat. Although the antitrypsin substances do not entirely explain the deleterious effect of raw soybeans, they constitute an important part of the effect. Under some conditions, this can be overcome by feeding the purified enzyme in combination with the raw protein, but this is not effective under all circumstances. Subjecting the soybean meal to moist heat treatment completely destroys the inhibitory properties and allows digestion to proceed normally (Renner and Hill, 1960b; Brambila et al., 1961). Gossypol, a toxic substance present in cottonseed, can interfere with digestion as indicated by reduction in the metabolizable energy of gossypol-containing diets (Hill and Totsuka, 1964).

A growth inhibiting effect characteristic of barley produced under dry farming conditions can be overcome by supplementing the diet with plant or microbial amylase preparations or by water treatment of the barley followed by drying (Jensen et al., 1957). A highly purified bacterial enzyme, beta-glucanase, is effective in very small amounts in improving the nutritional performance of barley, suggesting that the specific glucosidal linkages (beta-1,3 and beta-1,4) attacked by this enzyme may be the limiting factors in barley utilization (Ricks et al., 1962). It has been found that water treatment and the feeding of bacterial enzymes significantly increases the metabolizable energy of barley, indicating improvement in digestibility. The various findings suggest that the poor results from feeding this kind of barley are due to a specific deleterious effect of a specific indigestible carbohydrate—not merely to the fact that the carbohydrate value of the barley is somewhat reduced because part of it is indigestible.

Perhaps a parallel situation is involved in recent studies which have shown that certain natural gums, including the gums of guar and tragacanth, markedly inhibit the growth of chicks when fed at low levels (less than 5 per cent) in the diet (Kratzer and Vohra, 1963). The mechanism by which gums are inhibitory to growth is not known, but the observations suggest interference with the digestive process, as well as more direct inhibitory effects. Enzyme treatment of the gums has been effective in overcoming inhibition.

The characteristics of carbohydrates from various plant sources, or factors associated with them, may have important effects on utilization. Corn varieties containing a high proportion of the starch in amylose (linear) form have been shown to have markedly lower digestibility of starch than the usual varieties which have less amylose and a higher proportion of amylopectin (branched) (Borchers, 1962). Whether this is due to the glucosidic linkages in the respective starches or to factors of a different nature associated with starch configuration is not known.

The digestive efficiency and digestive capacity of birds is markedly stable. The value of a diet per unit weight, measured as metabolizable energy which indicates its over-all digestion, absorption, and utilization, is essentially unaffected by the level of feeding. Even conditions such as treatment with certain hormones which markedly increase the level of food intake above normal have no effect on the percentage digestibility or metabolizable energy per unit weight of the diet. Aside from some characteristics associated with the very young chick, there is essentially no effect of age on digestive efficiency, and differences associated with breed, sex, growth rate, etc., are evidently minor and of little practical significance.

In general, associative effects of food components do not occur. That is to say, the value of a food mixture is generally the sum of the individual values of its components. However, there are some interesting and important exceptions to this generalization. For instance, there may at times be an improvement in the absorbability of poorly utilized fats (such as beef tallow) or fatty acids when they are fed in combination with a highly absorbable fat, indicating that the properties of the mixture are not directly predictable from the properties of the component parts. Another example is the interference of certain diet components with the availability of certain minerals, particularly trace minerals. Feeding a high level of calcium, for instance, can interfere with the utilization of manganese. Furthermore, the availability of zinc seems to be reduced in the presence of soybean meal due to specific interference of the combination of calcium phytate and certain protein components with the absorption of zinc (O'Dell and Savage, 1960). The availability of zinc can be enhanced under these unfavorable conditions by adding to the diet chelating agents such as EDTA (ethylene diamine tetraacetic acid) (Kratzer et al., 1959). Such substances modify the solubility and ionic properties of metal ions, and thereby influence their availability to the animal. Other natural binding agents and chelating substances undoubtedly exist in foods and their hydrolysis products which can modify the utilization of required minerals. Some amino acids, and probably protein fragments as well, have chelating properties.

Minerals are absorbed and excreted in the gut by active transport mechanisms which are under the control of the systems which maintain constant composition of body fluids and structures (homeostasis). The extent of absorption of iron, for instance, is controlled according to need for synthesis of hemoglobin. It is considered likely that the state of an iron-binding protein in the intestinal tissues determines the amount of iron absorbed. The absorption of sodium, potassium, calcium, chloride, phosphate, and sulfate all have been shown to take place by active transport.

OTHER FUNCTIONS AND PROPERTIES OF THE DIGESTIVE SYSTEM

Though the digestive and absorptive functions of the gastrointestinal tract predominate, some biochemical processing also occurs in the gut tissues. One such process is the synthesis of vitamin A [com carotenoid pigments which serve as its precursors. Another, of course, is the synthesis of triglycerides and phospholipids from the digestion products of fats.

The significance of the microflora of the gut has been studied extensively in several ways. The chick was among the first animal species to be reared under germfree conditions, demonstrating that a normal bacterial flora is not necessary to life. Since the discovery that small amounts of antibiotics added to the diet of chicks can markedly stimulate growth, many investigations of the relation of diet and environment to gut flora and the antibiotic effect have been made. The concept now generally accepted is that antibiotics exert their favorable effect by overcoming inhibitory effects of the bacterial flora of the gut, based on three kinds of evidence. First, growth of chicks reared in clean quarters, uncontaminated by previous use for chickens, is not improved by antibiotic feeding; similar chicks in contaminated quarters commonly used for chickens show marked growth stimulation by antibiotic feeding, their maximum growth rate being equal to the chicks in the clean environment. This indicates a growth retarding effect associated with environment (Coates et al., 1952). Second, the growth stimulating effect does not occur under germfree conditions (Forbes and Park, 1959). Third, the establishment of a known, controlled microflora in chicks has shown a

marked inhibitory effect from *Clostridium welchii*, which was prevented by feeding penicillin (Lev and Forbes, 1959). The degree of response to dietary antibiotics has been difficult to relate to changes in intestinal flora, and it is unlikely that a single kind of inhibitory effect is involved under all conditions, but it is clear that the antibiotics exert their effects through the microflora.

Associated with the favorable effect of antibiotics on growth is a reduction in the weight and thickness of the intestine (Coates et al., 1955). The significance of this change is not known, but it suggests the possibility of improved gut function. Recently, it was reported that dietary metabolizable energy was increased significantly by antibiotic supplementation under conditions in which the growth of chicks was improved 10–20 per cent (Nelson et al., 1963).

In a sense, the lumen of the digestive tract is part of the external environment of the animal, and is subject to the external influences of food supply and microorganisms. It is quite remarkable that the conditions in the tract are maintained so uniformly, as indicated by such measures as the pH and the percentage of water in the gut contents (Lepkovsky et al., 1957). The relationship of host to microflora in poultry includes the inhibitory effect discussed above, but there are also favorable effects. Vitamin K and biotin are synthesized by the flora and absorbed in significant amounts by the chicken. Furthermore, the established flora may serve as a buffer to prevent invasion of the gut by more unfavorable microorganisms and may therefore represent the best compromise which can be achieved by the host animal in the prevailing environment.

Heredity and the Defective in Poultry

Changes in all phases of the poultry industry have been rapid and have led to changes in patterns of pathological problems. Certain salient facts are mentioned to focus attention on the biological complexity involved in production phenotypes of domestic poultry.

A major problem is the continued and considerable change in environmental conditions that man forces on his animals. The tendency is to consider egg layers, broilers, and turkeys as mass production units with machinelike performance rather than biological creatures, responsive to environmental stresses. The danger inherent in "intensivism" is that increase in stressors of all sorts can and do occur. Deep litter, no litter, slatted floor, wire floor, mechanical feeders, automatic egg-gathering devices, feeds designed to give a maximum of power for production, with high protein and high energy content, alteration in photoperiods, various kinds of confinement with their fatigue and social order prob-

lems are just a few of the "improvements" which are not entirely free of conditions contributing to pathological problems. Unfortunately the genetic adaptivity of the birds increases at a much slower rate than does the ingenuity of man in thinking up new ways to harass them.

There has been a gradual concentration of breeding stocks into a relatively few decision-making hands, so that there are few fountainhead sources of genetic material, and the resultant widespread dissemination of single source stocks has resulted in the loss of the isolation which occurs from many small breeder locations. This may be a potential means of speeding the dissemination of new or existing diseases. There has been a decided change in the type of commercial stocks with small-bodied, efficient egg-laying strains and rapid-growing, large, specialized varieties for meat production. Almost without exception the commercial bird is a result of a well-planned and tested cross. The con-

strands are coiled into a helix so that particular nucleotides pair across the interstices of the helix.

Adenine-thymine and guanine-cytosine are the variable bases in DNA which are involved in the genetic code. There is evidence that messenger ribonucleic acid (RNA) is involved as a transport unit between the blueprint DNA in the nucleus and the cytoplasmic RNA associated with the ribosomes which are the site of protein syntheses. The DNA-RNA instruction code is not only the biochemical carrier of information of the life process from one generation to the next, but also determines the development of the new individual. The directions are formed from chance combinations of DNA arrangements from the sire and the dam at conception. The blueprint for reaction to various environments is set at this time for the individual. How it fares depends upon its hereditary endowments and the severity of environmental conflicts.

Trait Expression and Variation

The "gene" locus concept as a physiologically differentiated chromosomal segment is a satisfactory representation of a hereditary unit for selection theory. The smallest hereditary unit for selection purposes is the individual bird: the unit used by the poultry breeder.

The phenotype or expression of a trait results from the combined influence of hereditary messages and environmental forces. The longer the chain of events between the first action of the "gene" and its final expression in the phenotype the greater the complexity of effects which can arise from a simple alteration in the molecular configuration. Much of the complexity of relation between "gene" and character is attributed to the multiplicity of stages intervening between initial action and final expression in a series of reactions, each requiring a characteristic primary action of a "gene." Some clear examples of this type have been described in Neuro-

spora by numerous investigators beginning with Beadle and Tatum (1941), and lead to the one gene-one enzyme hypothesis. Investigators have determined that specific loci do control specific enzymes, and defects in the message system result in a breakdown of biochemical processes at a variety of levels, any of which result in functional disturbances.

Variation

Studies in several species show that each carries a considerable proportion of loci and even chromosomal segments which seem less desirable than its alternate. It might be expected that the superior allel or chromosome would supersede the other through selection so that some sort of genetic uniformity would be found for the superior allel, but polymorphism seems to be the rule in many populations rather than the exception. At one time there was a widespread opinion that selection would result in the establishment of the more favorable allel in the homozygous state and produce the ultimate animal. However genetic variation in a population seems necessary for adaptivity. Lerner (1954) cites considerable evidence that continual selection and/or inbreeding (both result in a loss of heterozygosity) in populations of chickens almost invariably results in loss of fitness and eventually an attenuation of progress in selection. While the tendency for natural or wild populations is to be polymorphic, i.e., to exhibit a wide range of genetic diversity, it is not established that domestic poultry need be as heterogenous.

Genetic Variation in Parasitic Invaders

The parasite, according to Sprent (1963), is any organism which can use or requires the tissues of another in part or all its life cycle. The heteroparasites are phylogenetically distinct from the host and include viruses, mycoplasmetales, rickettsiae, bacteria, molds, protozoa, worms, arthropods, etc.

trol afforded by this type of breeding and multiplication as well as the high-level performance obtained suggest that such crossing systems will persist for some time. Attention is no longer required by the breeder and flock owner to certain of the standard breed and variety defects.

There are also changes in patterns of disease incidence as poor viability stocks have been eliminated and improvement has been made in the livability of surviving strains and crosses. Some indication of this is shown in comparisons of random sample egg-laying test reports such as made by McClung (1961). It is obvious that a good deal of the competitiveness of the surviving commercial varieties is due to their superior viability.

Increased densities give greater opportunities for infective organisms to build to high concentrations and nonpathogenic organisms to become pathogenic or at least harmful secondary invaders. There seems to be an increased susceptibility to organisms normally protected against by supposedly innate resistance mechanisms. Examples of these include high early-age losses in broiler stocks from the leucosis complex, increased incidence of lymphomatosis in turkeys, and occasional epidemics of blackhead in chickens.

The increased and combined use of antibiotics may result in the evolution of new and resistant pathogenic invader types. This has been demonstrated in both penicillin and streptomycin resistance of certain microorganisms. Widespread use of antibiotics may create a risk where Salmonella and the like are a menace to man. If resistant strains are involved these agents may not respond to therapeutic use of antibiotics. Appearance of atypical forms of various common agents, such as variant forms of *Salmonella pullorum*, can always be expected to occur occasionally even without an antibiotic as a screening agent.

There has been a reduction of certain diseases through eradication methods. These include the reduction in avian tuberculosis in all pullet flocks, and eradication and prevention methods which have been effective in reducing pullorum outbreaks, although on the whole control and eradication methods have failed to eliminate the Salmonella infections. Newcastle disease in Britain did not yield to the slaughter policy. The efforts to establish PPLO-free breeding flocks have only been partially successful. Part of these failures can be blamed on not following the rules, but the biological principles involved are obviously not fully understood.

THE GENETIC MECHANISM

Chickens and other poultry are complex systems with a built-in direction for life functions. This blueprint for development and reproduction of its kind is contained in the chromosomes of the cell nucleus. Variation in the genetic direction system as well as environmental effects have a profound influence on the well-being of the organism. There seems to be a certain mysticism about genetics caused largely by the definition of a "gene" and the uncertainty of quantitative traits which seem to be only vaguely controlled by genetic mechanisms. Recent findings in cellular biochemistry and population genetics have advanced our understanding of these factors and the part they play in species preservation. It should be kept in mind that a gene has never been more than a postulate to explain an actual occurrence. It has been generally supposed that the genes or determiners were molecular in nature. Knowledge about the hereditary material suggests that there is in fact a precise molecular template. The hereditary material consists principally if not entirely of deoxyribonucleic acid (DNA) which is a long chain of four repeating nucleotides. Each nucleotide is composed of deoxyribose, phosphoric acid and either a purine or pyrimidine base. The long chain of nucleotides is believed to be one strand of the two-stranded chromosome. According to Watson and Crick (1953) the double

segregations affecting form and function, some of which are lethal or sublethal in nature. Landauer (1951) listed 17 lethals affecting embryonic development. Several more have been subsequently reported.

The rather simply inherited patho-genetic situations and genetic abnormals have been classified and discussed by both Hutt (1949) and Jull (1952). They report in some detail a considerable number affecting the skeleton, feathers, and organs. Waters and Bywaters (1959), authors of the chapter on genetics in the fourth edition of this book, also cite several examples. A number of genetically interesting and physiologically important ones have since been reported, principally in *Poultry Science* and the *Journal of Heredity*. It is entirely likely that there are many abnormalities ranging in effect from lethal to subvital which are never investigated. Hutt (1961b) has pointed out that complacency about these in poultry is ill advised as the number of the inherited genetic defects may in fact be much greater than now thought and advises vigilant breeding practice for an elimination of such defects.

The "genetic load" or proportion of subvital loci which populations carry is much greater than was once supposed, as suggested by extensive studies in various laboratory species. In most cases natural selection and/or selection by the breeder seems to have minimized the genetic load in the domestic fowl and detrimental recessives have had little effect on production performance. Sometimes in closed population such as inbred lines there is added effort to purge undesired deleterious recessives. Those with clearcut segregation are more or less automatically eliminated in the surviving inbred lines. Because of the high reproductive rate, relative cheapness, and general lack of sentiment attached to the individual chicken, extensive culling has prevented some of the devastation that has occurred in certain of the highly regarded registered cattle herds.

Any genetic mechanism which gives rise to polymorphism such as heterozygote superiority (overdominance) either per se or through close linkage of positive fitness loci with deleterious loci may discourage elimination of undesirable loci. Such loci as self-sterility allels or miotic drive and segregation distortion situations as reported in mice by Dunn (1957) and drosophila by Sandler (1962a and 1962b) are self-perpetuating.

Chromosomal Aberrations

Few of these have been recorded in poultry, largely because of the complex and obscure cytogenetic situation. However, it seems reasonable to suppose that these exist since they have been reported in drosophilia, maize, mice, and man in which there has been cytogenetic exploration. Bernier (1960) reports a 50 per cent lethality from appropriate matings which could be explained by a translocation or similar chromosomal aberration, although no cytological evidence was obtained. Newcomer (1959) described the cytological appearance of a translocation induced by X-rays in a carrier sire from the University of California flock.

In general, these sorts of genetic disturbances are not likely to be of economic importance unless there is a situation similar to that described by Dobzhansky (1955) for *Drosophila pseudoobscura* in which inversion heterozygotes were highly viable. The chromosome abnormalities were kept in the population at a high frequency even though the homozygotes were lethal. The inversions are equivalent to singly powerful loci, which substantially reduce the fitness of the population as a whole.

Phenodeviants

Lerner (1954) defined "phenotypic deviants as sporadic and ubiquitous for a given species, but which fail to exhibit clear-cut mendelian inheritance." A principal example, certainly encountered by every poultryman, is the crooked toe trait. Nutritional deficiencies, faulty incubation, wire floors, and other environmental influ-

The higher forms of parasitic organisms in the main are diploid and sexual reproduction with the usual results from recombination, segregation, independent assortment, and mutation provide for genetic variety as in poultry. However, the bacteria and viruses have vegetative reproduction and are haploid, so mutation is a major source of new genetic variation. Vegetative reproduction through duplication of the chromosome and transmission of these to each daughter cell continues identical heredity. Even though mutation of the spontaneous variety occurs only rarely (probably at a no higher rate than in more complicated organisms), the haploid condition in a rapidly reproducing organism, where one cell in suitable conditions may give rise to several million cells in less than 24 hours, provides considerable opportunity for selection to preserve new types. Recombination in bacteria has several mechanisms, conjugation, transformation, and transduction, although not of the ordinary crossing over type as in diploid organisms. The genetic flexibility of the microorganism is considerable with its potential reproductive, recombinational, and mutational abilities for meeting new environments.

Conjugation was described by Lederberg and Tatum (1946) in *E. coli* in which two cells fuse and form a cytoplasmic bridge with the chromosomes of the donor being injected into the recipient.

Transformation in bacteria was reported by Avery *et al.* (1944). DNA extracts have been made from streptomycin-resistant bacteria, and this extract placed in the growing media of streptomycin-sensitive cells. Many of the sensitive strain were converted to resistant cells and, furthermore, passed this resistance to their progeny. This permanent change in heredity is an extraordinary phenomenon of random transfer of genetic material, rather than the ordered sequence as in the usual gametic situation.

Transduction in bacteria was described by Zinder and Lederberg (1952). During the infective stage the bacterial virus or bacteriophage attaches to the cell wall and empties its DNA contents into the bacterium. The DNA of the phages uses the bacterial cell contents to replicate itself. The bacterium is lysed, and the newly replicated phages are released into the medium. During the process of replication, the DNA of the host bacterium is used by the invading phage and more or less remade to fit its own pattern. Occasionally it carries along part of an intact message of the bacterium as well. This has been shown by infecting a resistant strain where-in the viral DNA occasionally attaches to the chromosome of the host cell and multiplies as if part of the host chromosome. This phenomenon is called lysogeny. The startling and interesting thing is that every so often a resistant bacterial cell will emerge. Thus a genetic message of one bacterium is carried by a virus to another bacterium.

PATHOLOGICAL CONDITIONS ASSOCIATED WITH HEREDITY

The relation of genetics to disease is undoubtedly one of the intricate and exciting aspects of pathology. Biologists are gradually unraveling the relationship of genetic framework and environmental interaction within which life processes exist. Certain of these relationships are clear as with certain of the simply inherited defects in form and function. Others are not as well understood, but show that different genomes of varieties, species, and individual members of each contain combinations of hereditary directions which are responsible for abnormals and nonviables. The pathological condition deviates from the normal and usually affects the well-being of the individual. Thus fitness is reduced so that the opportunity for maximum performance and the leaving of offspring is hindered or abolished. Those abnormal conditions which are due to mistakes in the genetic code (molecular or chromosomal) have been called congenital or innate. Many of these are single unit

segregations affecting form and function, some of which are lethal or sublethal in nature. Landauer (1951) listed 17 lethals affecting embryonic development. Several more have been subsequently reported.

The rather simply inherited patho-genetic situations and genetic abnormals have been classified and discussed by both Hutt (1949) and Jull (1952). They report in some detail a considerable number affecting the skeleton, feathers, and organs. Waters and Bywaters (1959), authors of the chapter on genetics in the fourth edition of this book, also cite several examples. A number of genetically interesting and physiologically important ones have since been reported, principally in *Poultry Science* and the *Journal of Heredity*. It is entirely likely that there are many abnormalities ranging in effect from lethal to subvital which are never investigated. Hutt (1961b) has pointed out that complacency about these in poultry is ill advised as the number of the inherited genetic defects may in fact be much greater than now thought and advises vigilant breeding practice for an elimination of such defects.

The "genetic load" or proportion of subvital loci which populations carry is much greater than was once supposed, as suggested by extensive studies in various laboratory species. In most cases natural selection and/or selection by the breeder seems to have minimized the genetic load in the domestic fowl and detrimental recessives have had little effect on production performance. Sometimes in closed population such as inbred lines there is added effort to purge undesired deleterious recessives. Those with clearcut segregation are more or less automatically eliminated in the surviving inbred lines. Because of the high reproductive rate, relative cheapness, and the general lack of sentiment attached to the individual chicken, extensive culling has prevented some of the devastation that has occurred in certain of the highly regarded registered cattle herds.

Any genetic mechanism which gives rise to polymorphism such as heterozygote superiority (overdominance) either per se or through close linkage of positive fitness loci with deleterious loci may discourage elimination of undesirable loci. Such loci as self-sterility alleles or miotic drive and segregation distortion situations as reported in mice by Dunn (1957) and drosophila by Sandler (1962a and 1962b) are self-perpetuating.

Chromosomal Aberrations

Few of these have been recorded in poultry, largely because of the complex and obscure cytogenetic situation. However, it seems reasonable to suppose that these exist since they have been reported in drosophila, maize, mice, and man in which there has been cytogenetic exploration. Bernier (1960) reports a 50 per cent lethality from appropriate matings which could be explained by a translocation or similar chromosomal aberration, although no cytological evidence was obtained. Newcomer (1959) described the cytological appearance of a translocation induced by X-rays in a carrier sire from the University of California flock.

In general, these sorts of genetic disturbances are not likely to be of economic importance unless there is a situation similar to that described by Dobzhansky (1955) for *Drosophila pseudoobscura* in which inversion heterozygotes were highly viable. The chromosome abnormalities were kept in the population at a high frequency even though the homozygotes were lethal. The inversions are equivalent to singly powerful loci, which substantially reduce the fitness of the population as a whole.

Phenodeviants

Lerner (1954) defined "phenotypic deviants as sporadic and ubiquitous for a given species, but which fail to exhibit clear-cut mendelian inheritance." A principal example, certainly encountered by every poultryman, is the crooked toe trait. Nutritional deficiencies, faulty incubation, wire floors, and other environmental influ-

The higher forms of parasitic organisms in the main are diploid and sexual reproduction with the usual results from recombination, segregation, independent assortment, and mutation provide for genetic variety as in poultry. However, the bacteria and viruses have vegetative reproduction and are haploid, so mutation is a major source of new genetic variation. Vegetative reproduction through duplication of the chromosome and transmission of these to each daughter cell continues identical heredity. Even though mutation of the spontaneous variety occurs only rarely (probably at a no higher rate than in more complicated organisms), the haploid condition in a rapidly reproducing organism, where one cell in suitable conditions may give rise to several million cells in less than 24 hours, provides considerable opportunity for selection to preserve new types. Recombination in bacteria has several mechanisms, conjugation, transformation, and transduction, although not of the ordinary crossing over type as in diploid organisms. The genetic flexibility of the microorganism is considerable with its potential reproductive, recombinational, and mutational abilities for meeting new environments.

Conjugation was described by Lederberg and Tatum (1946) in *E. coli* in which two cells fuse and form a cytoplasmic bridge with the chromosomes of the donor being injected into the recipient.

Transformation in bacteria was reported by Avery et al. (1944). DNA extracts have been made from streptomycin-resistant bacteria, and this extract placed in the growing media of streptomycin-sensitive cells. Many of the sensitive strain were converted to resistant cells and, furthermore, passed this resistance to their progeny. This permanent change in heredity is an extraordinary phenomenon of random transfer of genetic material, rather than the ordered sequence as in the usual gametic situation.

Transduction in bacteria was described by Zinder and Lederberg (1952). During the infective stage the bacterial virus or bacteriophage attaches to the cell wall and empties its DNA contents into the bacterium. The DNA of the phages uses the bacterial cell contents to replicate itself. The bacterium is lysed, and the newly replicated phages are released into the medium. During the process of replication, the DNA of the host bacterium is used by the invading phage and more or less remade to fit its own pattern. Occasionally it carries along part of an intact message of the bacterium as well. This has been shown by infecting a resistant strain wherein the viral DNA occasionally attaches to the chromosome of the host cell and multiplies as if part of the host chromosome. This phenomenon is called lysogeny. The startling and interesting thing is that every so often a resistant bacterial cell will emerge. Thus a genetic message of one bacterium is carried by a virus to another bacterium.

PATHOLOGICAL CONDITIONS ASSOCIATED WITH HEREDITY

The relation of genetics to disease is undoubtedly one of the intricate and exciting aspects of pathology. Biologists are gradually unraveling the relationship of genetic framework and environmental interaction within which life processes exist. Certain of these relationships are clear as with certain of the simply inherited defects in form and function. Others are not as well understood, but show that different genomes of varieties, species, and individual members of each contain combinations of hereditary directions which are responsible for abnormals and nonviables.

The pathological condition deviates from the normal and usually affects the well-being of the individual. Thus fitness is reduced so that the opportunity for maximum performance and the leaving of offspring is hindered or abolished. Those abnormal conditions which are due to mistakes in the genetic code (molecular or chromosomal) have been called congenital or innate. Many of these are single unit

thesis. The Australorps were either unable to carry out the synthesis or else did so at an inefficient level. Hess et al. (1962) were able to differentiate lines into high and low methionine requirement through selective breeding. McDonald and Beilharz (1962) reported differences in calcium metabolism between strains of White Leghorns and Australorps which lead to a genetic susceptibility to low calcium rickets in the Australorps. Differences of genetic origin have been reported for utilization of vitamin D by Lillie and Bird (1949), and of vitamin E by Howes and Hutt (1952). Genetic differences in arginine requirement among White Leghorns were reported by Nesheim and Hutt (1962).

Kondra and Hodgson (1961) reported genetic differences in energy-protein requirements of chickens, as did Siegel and Wisman (1962). Nordskog and Johnson (1953) found a significant breed-antibiotic level interaction for growth to eight weeks of age. Arroyave et al. (1957) found genetic differences between and within breeds in nutrient content of eggs. McNary and Bell (1957) reported a reciprocal maternal effect in which the egg contained either a growth depressant or a nutritional deficiency.

Stutts et al. (1957) and Wilcox et al. (1962) found genetic differences in levels of a blood enzyme, serum alkaline phosphatase, which were related to egg production. The latter authors were able to select differentially for high and low lines. Glutathione concentration had a genetic correlation to level of egg production according to Stutts et al. (1956). All of the cited investigations are either directly or indirectly implicated in pathological conditions and most certainly are concerned with the viability of the bird under domestic conditions.

Immunogenetics

There has been considerable investigation in the fowl regarding the immuno-genetic relationship of the antigen-anti-

body reaction of red blood cells, the homograft transplantation reaction and the graft-against-host reaction. The investigations of Schierman and Nordskog (1961 and 1963) have shown that the B blood group locus is a major histocompatibility locus. The skin-graft and graft-against-host reactions are intimately related genetically to this locus in the chicken. Since these or similar types of reactions are involved in defense mechanisms and in some way seem to have importance in survival value it seems appropriate to discuss them at this point. No antigenic reaction has been described such as the human Rh complex which leads directly to a pathological condition.

Blood Grouping

Some six loci for red cell antigens have been identified through agglutinating iso-immune sera in the domestic fowl. Genetic tests indicate that each are located at different chromosomal regions. Presumably these loci are on different or nonhomologous chromosomes.

Certain combinations of blood group loci, and the B group in particular, confer or are associated with viability either during embryonic, growing, or adult stages of the chicken's life. There is evidence that the heterozygous condition has superiority to one or both homozygotes in the majority of cases studied: Briles et al. (1950), Schultz and Briles (1953), Briles et al. (1953), Gilmour (1954), Briles and Krueger (1955), Briles (1956a, b, and c), Briles et al. (1957), Gilmour (1959), Gilmour (1960a and b), Allen (1960), Fanguy et al. (1961), and Bumgardner et al. (1961). These findings suggest that the loci for chicken red cell antigens are in a state of balanced polymorphism, i.e., enforced heterozygosity, because of general fitness superiority. In any case there is no clue so far as to how or why the identified loci confer the apparent fitness. Certain of the theoretical implications and applied breeding aspects are discussed by Briles (1956b and c) and Gilmour (1960b and 1962).

ences affect the appearance of this abnormality. Certain strains have been known to show this defect more than others in indicating a feasible genetic influence. Hicks and Lerner (1949) found that certain inbred lines had a high incidence. Also incidence could be increased and decreased through selection. However, there seem to be few if any cases of simple segregation ratios found in breeding tests for crooked toes in the domestic fowl.

The anomaly of crooked keels which has plagued poultrymen for years likely falls into a similar category of a character determined by and conditioned in its expression by known environmental situations, such as roosts and vitamin D, with a high incidence in certain strains and lines. The genetic situation as reported by Warren (1937), Waters (1949), Shoffner et al. (1953), Hyre (1955), and Shoffner and Canfield (1957) shows that incidence may vary greatly depending upon genetic background.

The self-dubbing trait reported by Bernier (1961), the baldspot and cleft-palate traits by Shoffner et al. (1953), and the multiple side sprig condition by Taylor (1946) all have obvious phenotypic expression but ill-defined genetic influences. The fact that these traits appear more or less unexpectedly and have been observed in many flocks of chickens suggests that these, and other characters with similar action, are conditioned by numerous loci, and when a certain fraction becomes homozygous the trait is expressed. In a fairly large interbreeding flock the trait appears only occasionally, but if there is concentration of ancestry either through selection or deliberate inbreeding, homozygosity can increase the incidence.

PHYSIO-BIOCHEMICAL GENETIC VARIATIONS

Dietary and Metabolic

Some of the better known mutant forms in molds and bacteria which are simply inherited are concerned with nutritional capacities and synthesis from crude products to the more refined constituents needed in metabolism. It is well known that nutritional deficiencies in poultry not only produce specific pathological conditions, but can also contribute to susceptibility or resistance to invading parasites. In general, attempts to modify diets through superabundance of vitamins, amino acids, or growth factors in an attempt to increase resistance have been ineffectual according to Hill (1962). Therapeutic levels of antibiotics are obvious exceptions.

Nearly everyone who has studied the question of existing differences in dietary requirements, utilization, or metabolism of poultry, has found that families, lines, strains, and breeds do show differences Unfortunately, in most cases our knowledge goes little beyond this demonstration. Fortunately it does emphasize that such discrepancies do exist, and such investigations will contribute to our knowledge of the biology of the fowl. Just when extensive investigation of these inherited differences will lead to an applied breeding program for increased fitness and performance is difficult to diagnose.

Hutt (1949, 1958) has reviewed the literature relating to genetic differences in diet utilization in chickens. Genetic differences have been demonstrated for thiamine requirement by Howes and Hutt (1956), Thornton (1960), Lamoreux and Hutt (1939), and Roberts (1962).

Differences in inherited capacity to utilize riboflavin was shown by Lamoreux and Hutt (1948). Maw (1954) reported a recessive single gene mutant involving the metabolism of riboflavin. The homozygous adult female is unable to transfer sufficient riboflavin from the diet to the egg for embryonic growth and development. Cowan et al. (1961) have shown that the normal laying hen retained free riboflavin more effectively than the laying hen which was homozygous recessive for this trait.

McDonald (1957, 1958) found breed differences between White Leghorns and Australorps in methionine and cystine syn-

secondary in occurrence rather than a primary causative factor. Kondra and Cavers (1947) found that the incidence of keel cysts was intimately related to the rate of feathering, particularly in the region of the keel, and concluded that the appearance was largely a defense mechanism. Gyles et al. (1959), Shoffner and Canfield (1957), and Hyre (1955) have presented evidence that the presence of keel cysts and other deformities of this region are influenced to some degree by heredity. Gyles et al. (1962) differentially selected for high and low incidence lines in a heavy broiler strain. They found the heritability for incidence of the blisters to be between 16 and 24 per cent in the high incidence line and zero in the nonblister line.

Climatic

Hutt (1938), Kheireldein and Schaffner (1957), and Huston et al. (1957) have variously demonstrated that there are genetic differences in susceptibility to controlled high temperatures. These temperatures were extreme, acting as a "stressor" to the point where some individuals would succumb. Campos et al. (1960) showed that there were breed differences in performance responses to fast and slow rises in ambient temperature. Siegel and Mueller (1955) reported that outbreds and crossbreds had greater resistance than inbreds to exposure to low temperature.

A very interesting contrast to extreme external environment was the result reported by Greenwood (1958) on the longterm effects of a constant environment. Birds maintained in a climatic chamber with constant environment did not perform as well as controls influenced by naturally fluctuating climatic conditions. Both Greenwood (1958) and Wilson (1958) reported that the constant environment resulted in almost complete incidence of adenocarcinomata involving tumors of ovaries and oviducts.

Feeding Practices

A currently widespread commercial practice is to restrict intake of feed for replacement pullets for both broiler breeder females and egg production stocks. In general the restriction practice delays sexual maturity and shifts the egg laying pattern and usually improves laying house livability. The publications of Hollands and Gowe (1961) and Gowe et al. (1960 and 1962), in which careful and extensive investigation of response of different genotypes were observed for both full and restricted feeding, reported that the restricted birds had higher livability during the production year. Different strains, though varying among themselves in viability, tended to maintain their rank in either environmental treatment.

Biely and March (1959) placed strains of White Leghorns, both resistant and susceptible to the avian leucosis complex, on high and low planes of nutrition. All strains on the high plane of nutrition had a greater incidence of avian leucosis complex. Waters et al. (1950) found in certain inbred lines of White Leghorns developed for resistance and susceptibility to the avian leucosis complex that there were genetic differences in livability for the first 21 days after hatching. Modification in the starting diet markedly altered the mortality pattern.

Location Effects

Experimental and commercial strains have been compared under a variety of environmental conditions, including such comparisons as cage vs. floor, farm to farm, one random sample egg laying test to another, and time of year to time of year. While management practices of comparisons vary, a not surprising suggestion is that infectious agents of one kind or another are involved in the genotype-environmental interaction observed. That is, the discrepancies between levels of performance in the different locations are due to morbidity and/or mortality from uncontrolled and unrecognized infections. The essence of this problem resolves to whether the top genotypes consistently do better under various environments or if there are significant interactions; if so,

Graft-Against-Host Reaction

This is a reaction of an immunologically competent graft against the foreign antigens of the host. In the cases cited here the host is a chicken embryo, presumably immunologically incapable of producing antibodies. Burnet and Burnet (1960 and 1961) found clear genetic segregation for graft-against-host reaction of adult leucocytes on the chorioallantoic membrane of the chick. Jaffee and Payne (1962) presented evidence for inheritance of differences of the graft-against-host reaction between two inbred lines of chickens which differed in at least one major locus determining antigens responsible for the splenomegaly reaction in the embryo.

Host-Against-Graft Reaction

This sort of reaction commonly occurs when grafts of tissues and organs are made from one individual to another. When antigens of host and donor are the same (twins and members of isogenic lines) the reaction does not occur. Craig and Hirsch (1957), Craig et al. (1960), Berry and Craig (1959), and Polley et al. (1960) have shown that there are genetic differences in skin graft histocompatibility reactions of chickens.

GENETIC-ENVIRONMENTAL INTERACTIONS

The experienced biologist recognizes from long experience that a variety of environmental influences may "stress" an organism to the point of disorganization. Development of specific management practices in intensification has led to investigation as to whether there are definite and repeatable genetic effects and whether strains perform differently in various environments.

Social Order

The hierarchical social system or peck order in the domestic fowl is intimately related to temperament and husbandry practices. The publications of Guhl (1953 and 1962) have summarized the investigations which have shown rather clearly the relationship between social rank and productivity. The ones on the low end of the social scale are usually below normal in their physical state and sometimes are at the point of starvation. McBride (1958, 1960, and 1962) presents evidence to support the hypothesis that the curvilinear relation of productivity and rank depends to a large extent on availability of feed, water, bird density, and other management factors.

Behavior per se is not inherited but certain genotypes have different physiological responses to stimuli. Certain strains of chickens dominate others in mixed groups. Temperament is not presently definable in simple genetic terms, except that certain strains are reproducibly and predictably dominant or subservient. Guhl (1953), Tindell and Craig (1959 and 1960), and Guhl et al. (1960) have demonstrated that genetic variation in social aggressiveness and competition effects exists within strains, between sire families, strains, inbred lines, and crosses. Selection for high and low aggressiveness showed considerable response.

Dickerson et al. (1961) investigated the heritability for picking behavior in chickens and found it to be low. The measurable heritable differences were among sire and dam families for aggressiveness. Whether social aggressiveness is intimately tied in with such vices as feather picking, vent picking-prolapse, or other cannibalistic habits is difficult to ascertain as prolapse is presumed to be physiologically unrelated. Practical experience has shown that some strains of birds are more prone to these tendencies than others. There has been discrimination by the producer in recent times against strains with prolapse tendencies.

Breast Blisters

The incidence and size of keel cysts on growing chickens and turkeys depends upon inherited tendency, type of floor, moisture in the litter, and micro-invaders, although it would seem that the latter are

little or no selection progress due to the low heritability of viability.

Resistance measurement usually is a discontinuous variable: either the individual has a pathological condition or it has not. However, morbidity may be graded into classes of low, medium, and high. In cases where resistance or nonresistance is measured by death, the trait becomes all-or-none, and groups are divided into those that die and those that survive. It is generally assumed that the genotypes form a continuous scale for resistance, but because of the threshold manifestation, phenotype is a discontinuous variable. As a result the geneticist often converts to some scaling method such as probits which are amenable to statistical manipulation. Certain of the pertinent considerations and useful genetic techniques for viability selection are discussed by Lerner (1958) and Falconer (1960).

CONSIDERATIONS IN RECOGNIZING RESISTANCE

With few exceptions, the investigations of resistance in poultry have explained little about pathways and mechanisms involved for either general or specific manifestation of resistance on the part of the host to pathogenic organisms. Mention is made here of certain of the recognized protective mechanisms involved in resistance as a reminder that several pathways and physiologic reactions may be involved and to focus attention on the precautions necessary in a resistance recognition program. Knowledge of principles involved in immunity and resistance are more valuable than merely recognizing resistance. The answer to whether resistance is through some barrier excluding entry of the organism or is through ability to harbor the agent and not succumb will permit a more knowledgeable approach to a selection program or any plan for protection against the pathogen. The possibility of using physio-chemical tests to predict biological fitness is attractive to reduce cost and increase accuracy. A perfect correlation between a biophysical measurement and viability does not increase the heritability of the viability trait. It may, however, provide an early, inexpensive, and accurate estimate of final performance. A physiological or biochemical measurement in a parent may predict the viability of progeny to a higher degree than does the viability of the parent.

Kinds of Immunity

In innate immunity the internal or external environment of the host is entirely unsuitable for the invader, and includes such things as age, body temperature, and anatomical and physiological differences. Frequently innate means we do not know why one organism is not readily infected by another, it just is not.

Natural immunity mechanisms are of a considerable variety and include the following: entry surfaces which are barriers to infection by secretion of such antiparasitical substances as lysozyme, fatty acids, high and low pH, etc.; antiparasitical substances in the blood or other body fluids which include antibodies, antienzymes, lactic acid, blood complement, and gamma globulins; and the phagocytic system which is a universal and fundamental mechanism in resistance. There are individual differences in ability to form antibodies and in ability to ride out an infection until time has been gained for manufacture of antibodies.

Acquired immunity is not necessarily a characteristic of the species but varies according to the history of infection of the individual, much like protective immunization. Passive immunity such as that passed through the egg to the chick is not lasting, and others of this sort may very well obscure natural abilities for resistance.

Hypersensitivity or allergic reactions are frequently associated with worm and arthropod infection and may be of considerable significance in preventing the penetration of metazoan parasites.

Ecological immunity occurs when the characteristic behavior and feeding habits

little or no selection progress due to the low heritability of viability.

Resistance measurement usually is a discontinuous variable: either the individual has a pathological condition or it has not. However, morbidity may be graded into classes of low, medium, and high. Hypersensitivity or allergic reactions are frequently associated with worm and arthropod infection and may be of considerable significance in preventing the penetration of metazoan parasites.

Ecological immunity occurs when the characteristic behavior and feeding habits

are such that neither nonexposure nor non-infection can take place.

CONSIDERATIONS IN DETECTING RESISTANCE

Specificity

The specificity of resistance is due largely if not entirely to the specificity of antigen-antibody reaction. The synthesis of a specific globulin involves the production of a specific pattern to the antibody molecule which renders the antibody capable of reacting only with the corresponding or closely related antigen. Likewise, genotypic resistance to a particular organism is specific as continually found by those involved in their immunological procedures and selective efforts to increase resistance.

Examples of specific resistance are shown in the findings of Cole (1941), Carson (1951), and Patterson et al. (1961) where stocks resistant to one infective agent were not necessarily resistant when exposed to other agents. This is convincing evidence that selection for specific resistance rarely results in over-all resistance. Waters and Burmester (1963) emphasize the fact that a specific strain RPL 12 virus and specific isolate genotypes (inbred lines) were instrumental in pinpointing the mode of inheritance to erythroblastosis.

Etiology

The fact that resistance exists and can be increased by selection without a complete knowledge of the etiology, as for example that for the avian leucosis complex, does not minimize the importance of knowing the etiology. Chronic respiratory disease with multiple etiology, according to Chu (1962), is another example of the complexity of a disease. If one organism gives multiple or variable syndromes or if several organisms give a similar clinical syndrome, there will be uncertainty about control measures until cause and effect are determined.

Exposure

Obviously unless and until individuals are exposed there is no way of recognizing their ability to resist an infectious agent, except for a predetermined relationship with some other physiological trait. One alternative is to use collateral family information, i.e., expose a portion of a stock and use nonexposed full sibs, half sibs, or progeny-tested parents for the production of progeny. This bypasses reproductive and dissemination problems from exposure but in no way lowers the requirements of exposure technique in the portion of the population tested. At least half of the genetic variance information contributing to selection progress is lost in going from the individual to information from relatives. The opportunity for mistakes in selection is obvious when only a part of the population is exposed. Unfortunately conditions of natural exposure often do not completely expose the entire population. Occasionally, natural infections may go undetected as in some respiratory diseases where infection was not suspected until subsequent tests disclosed high titers.

The relationship between responses to natural and artificial exposure and whether or not such responses are controlled by the same genetic factors are considerations in ensuring adequate exposure and constant selection pressure. Tests of correlation between inoculation, Champion (1954), sporulated oocysts; Heisdorf et al. (1947), with oral dosage; and Burmester et al. (1953), with cell-free extracts and natural exposure were reasonably satisfactory. Goodwin's (1957) description of the method and result of proximity brooding of chicks to carrier hens (leucosis complex) in an effort to ensure equal and adequate exposure suggests that this method is not entirely satisfactory. The numerous and uncontrollable factors such as transfer of passive immunity to progeny by parents with latent infection (Burmester, 1955 and Burmester et al., 1957) are a continual threat to evaluation of resistance.

Exposure to infective agents under natural conditions is sporadic so that occasionally the survivors of infection may not have their progeny rechallenged by the same agent for many generations. Mean-

while natural selection may be assorting the genotype in another direction. Under artificial selection conditions, however, persistant and renewed pressures are the ones that will establish new and improved levels of resistance which becomes a part of fitness.

MODES OF RESISTANCE IN THE FOWL

Certain of the phenomena and manifestations mentioned in this section are clearly associated with differential viability. However, it should not be construed that these are in themselves either cause or effect but are likely stages or states in which the physiological response can be recognized.

Heterosis

The phenomenon of increased vigor on crossing is well recognized in both plants and animals and, in general, the more isolated or inbred the populations, the greater will be the performance of the cross over the parent stocks. Embryo viability is almost universally increased as the result of crossing according to Warren (1942), Hutt (1919), Warren (1958), and especially if the female parent is a cross according to Shoffner (1948). However, King and Bruckner (1952) found little if any increase in hatchability of strain and breed crosses over parent stocks. As a general rule heterotic viability effects are pronounced during the brooding and rearing period as indicated by Warren (1942), Goodwin et al. (1956), and Hutt (1919). Siegel and Mueller (1955) found that outbred and crossbred chicks had a greater relative resistance to a low temperature exposure than did the chicks from either parental stock.

A proportion of experimental crosses shows an increase in adult or laying house viability. Goodwin et al. (1956) reported that strain-cross progeny were superior in pure-strain progeny in ability to withstand certain respiratory infections in layinghouse adults. Others, such as King and Bruckner (1952), found no difference between parent stocks and their crosses in total mortality and occurrence of mortality

due to neoplasms. The expectation for increased adult viability in the cross has been notably violated in the reduction of mortality from the leucosis complex. Hutt and Cole (1952) reported that the cross progeny of two White Leghorn strains relatively resistant to leucosis had slightly higher rate of death from neoplasms than progeny of either parent stock. Waters (1951b) using a series of crosses between inbred lines which varied in degree of resistance to avian lymphomatosis found no decrease in mortality from the inbred parent stocks. Bearse et al. (1961 and 1963) reported that leucosis mortality was not altered by the crossing of selected resistant and susceptible lines although there was lowered mortality from other causes. These experiences suggest that heterotic vigor per se will not automatically confer increased resistance to the avian leucosis complex. This unpredictability or deviation from that expected undoubtedly has several possible explanations. One is that the hybrid provides a "better" environment for agents inducing the malignancy.

Reciprocal Effects

Warren (1912) brought attention to the fact that there was a noticeable difference in performance between reciprocal crosses of Leghorns and heavy breeds. Reciprocal differences for sexual maturity and broodiness had been noted in several previous investigations and confirmed in Warren's excellent study. Warren noted that when White Leghorn males were mated to Rhode Island Red females, the mortality of the progeny was higher than that from the reciprocal cross. Because of the error involved in the estimation of mortality, it was not immediately apparent that this phenomenon was a rather general rule. However, subsequent reports such as Warren and Moore (1956), Hutt (1961a), and others leave little doubt that differences between reciprocal crosses are real.

Nordskog and Phillips (1960) presented evidence to show that progeny of the White Leghorn male of a Leghorn heavy cross have higher mortality than the reciprocal

and suggested that the Leghorn sex chromosomes are in some way associated with adult mortality. Moultrie et al. (1953) crossed strains of White Leghorn and secured reciprocal differences and implied that maternal effects may account for the difference.

Allen (1962) attempted to distinguish the contribution of sex linkage and maternal influence in the Leghorn-heavy cross. He found as usual that the Leghorn male × Rhode Island Red female produced progeny with significantly lower adult viability than the reciprocal cross. A series of especially designed backcrosses were made to study the effect of extranuclear (maternal) influence. A "plasmon" effect was noted which was interpreted as an interaction of the sex chromosome of White Leghorn and extranuclear influence of the Rhode Island Red.

The progeny from a heavy male and Leghorn female not only have higher viability but also have a higher incidence of broodiness. While some speculation has been made regarding the association of broodiness and increased viability, the phenotypic correlation may be fortuitous as the same genes may or may not be involved nor even have common physiological relationships. The possible sex linked inheritance, maternal effects (both cytoplasmic and viral agents), and interrelationships of hormonal secretion may influence the differential response observed in this type of reciprocal cross.

Bursa of Fabricius

The bursa of Fabricius is the primary source (activator) and the spleen is inactive or secondary in the production of antibodies in the young chick. The researches of Jaap (1958 and 1960), Chang et al. (1955 and 1957), Oakberg and Lucas (1949), Oakberg (1951), Glick (1955 and 1960), and Sadler and Glick (1962) have demonstrated heritable differences in both size and antibody production. The size of the bursa apparently has a relationship with the quantity of antibody produced. The ob-

served higher viability of some strains seems associated with large bursa size. Just how this supposedly temporary mechanism fits into genetic resistance is not yet clearly defined.

Body Temperature

One of the innate mechanisms which may differentiate resistance to a specific organism from one animal to another is body temperature. Hutt (1955) and Lamoreux and Hutt (1939) found that White Leghorn chicks were able to raise their body temperatures more quickly than Rhode Island Reds. This supplied a lead to a possible physiological basis of resistance to Salmonella pullorum. Considerable investigation was reported at various times by Hutt and Scholes (1911), Ram and Hutt (1955), and Hutt (1958) in which the genetic resistance of chicks to Salmonella pullorum was associated with the ability to accelerate the transition from the poikilothermic state of the embryo to that of the homoiothermic during the first 10 days after hatching. The rise in total leucocytes in response to infection seemed not to be genetically differentiated. Hutt and Crawford (1960) found that selection in both Rhode Island Reds and New Hampshires for high and low body temperature was effective in differentiating lines after two cycles of selection.

Sex

The balance of sex hormones may influence the incidence of lymphomatosis as Burmester (1945) and Burmester and Nelson (1945) observed nearly double the incidence in females as compared to that of males. The influence of castration and sex hormones on incidence was studied and the lack of male hormone was implicated in the increased incidence of lymphomatosis found in females. The incidence of keel cysts is higher in males, largely because the smaller females feather somewhat faster over the keel area according to Kondra and Cavers (1947). Of course those pathological conditions associated with egg

laying such as cystic ovaries, ruptures, and prolapses are sex limited.

Age

The embryonic chick and newly hatched chick are immunologically incompetent. The susceptibility to coccidiosis decreases with age. Hutt *et al.* (1944) and Waters and Bywaters (1949) showed that early exposure of chicks to lymphomatosis will lead to much higher incidence of adult mortality from that cause than in chicks exposed later in life. Their findings lead to the well-known management recommendation of chick isolation from older birds which works so well.

EXPERIMENTAL

Inbred lines and other selected populations have identifiable and reproducible genotypes which should not be overlooked by the investigator as a means of comparison and identification in biological assay. The genetic variability, along with environmental sources of variance, influence assay methods for the estimation of the potency of drugs, antibiotics, vaccines, bacterins, virulence of microorganisms, isolation and identification of agents, resistance, and susceptibility. The variation between individuals may be so large that judgments from one or few are misleading; however, averages of a group are usually reliable for distinguishing differences in capacity.

Some of the selected and isolate genotype stocks which have facilitated certain prior investigation and should be invaluable for contemplated research are the following: the RPL inbred lines which are resistant and susceptible to leucosis according to Waters and Burmester (1963); strains resistant and susceptible to leucosis according to Hutt and Cole (1948); lines with differential body temperature according to Hutt and Crawford (1960); lines with increased bursa of Fabricius sire according to Jaap (1960); stocks with single gene segregates, stemming principally from highly inbred stocks, as blood group loci according to Briles (1956b); the Rous sarcoma and erythroblastosis loci according to Waters and Burmester (1963); and the riboflavin deficiency locus according to Maw (1954).

On the other hand, inbred or heavily selected stocks, even though relatively homogeneous genetically, may be more subject to extraneous environmental influences since they are frequently less adaptive than heterozygous stocks. Lerner (1954 and 1958) discusses the topic of genetic buffering in some detail and suggests that under adverse environmental conditions the heterozygote will be less variable than the homozygote. When testing for a universal hypothesis or application the use of several genetic sources of either outbred, randombred, or crosses in conjunction with different treatment levels will give results of a more reliable nature in that estimates for the relative magnitude of genetic, treatment, and interaction effects are obtained.

The clinician, diagnostician, practitioner, pathologist, and others occasionally have encountered unexpected and unexplained variations which have been laid to genetic causes. Some caution should be exercised, however, as other sources of variation may be involved in the aberrants observed. For instance, field observations oftentimes point to strain or breed specificities but more often than not a particular strain is associated with a particular environment whose peculiarities have distinct influences.

The adaptivity of the fowl is continually challenged because of changes in management practices. The quantitative variation in the several genotypes for resistance as previously described, suggest that many loci with different effects are concerned in their inheritance. Furthermore the complicating influence of other environments serves to obscure the heritability of any specific one. Consequently, the staggering investment in selective breeding for specific invader resistance as well as adaptation to climatic, nutritional, or intensivism extremes may be viewed by some as question

able. Especially this is true since the breeder is often unable to predict just what stress someone may impose on his stock, or whether there are enough potential customers for a special stock to justify the investment. Numerous unpredictable and peculiar notions by the poultry industry about certain genetically influenced traits have occurred in recent years. It has variously favored or discriminated against comb type, eggshell color, plumage color, and skin color so that these seemingly inoffensive characteristics became defectives.

Avian Hematology

Hematology is defined as that branch of biology which treats of the morphology of the blood and the blood-forming organs. When dealing with the variations of the blood, it is essential that one consider not only the cellular elements as they occur in the blood stream, but also the origin and relationship of the blood cells and the relations between blood cells and the cells of the connective tissues and the reticulo-endothelial system Many changes apparent in the peripheral blood are merely a manifestation of a reaction taking place in the blood-forming tissues themselves. Such changes should be studied at the site of primary disturbance in order to arrive at a clear understanding of the process. Poultry pathologists are becoming more concerned with diagnosis. These measurements are hindered by several factors in birds. Avian erythrocytes and thrombocytes are nucleated, and the blood clots very quickly. Hemoconcentration develops quickly in overheated, excited birds. Loss of blood as well as age, sex, season, egg production, and environmental conditions have been shown to alter the composition of blood.

The principal purpose of this chapter is to briefly outline the salient points of avian hematology. It will, therefore, be necessary to omit detailed discussion of many questions. Such discussions will be found in the references listed at the end of the chapter. The report of the conference on leukocyte functions contains a wealth of information of value to anyone interested in hematology (Gordon, 1955). The extensive atlas of Lucas and Jamroz (1961) beautifully illustrates the variety of blood cells in the chicken from embryonal age to adult as seen in film or imprint preparations. Their work is an excellent reference. The morphology and understanding of organization and relations of blood cells in tissues can be further developed from study of tissue sections under the light and electron microscopes. Correlation of all methods of study will lead to a sound knowledge

of the reactions of blood and blood-forming tissues in health and disease. The domestic fowl or chicken is the main subject considered in this chapter, and except where noted all discussion refers to it.

DESCRIPTIONS OF THE CELLS AND HEMOGLOBIN IN THE BLOOD

Numerous physiological factors influence the number of the various types of cells and the amount of hemoglobin found in the blood. For this reason it is not possible to give a single set of figures that may be regarded as fixed normal values. The data in Table 4.1 are to be regarded as approximate values for normal birds and should be used in connection with the knowledge available concerning physiological variations. The staining reactions of blood cells described here are those secured by the use of Wright's blood stain or the May-Grünwald and Giemsa combinations of blood stains.

Methods of Counting Blood Cells and Measuring Hemoglobin

Many procedures have been recommended for the enumeration of blood cells of birds. Since all blood cells of birds are nucleated, the methods commonly used for counting mammalian blood cells cannot be applied. Relatively little difficulty is encountered in counting erythrocytes, but the counting of leukocytes introduces certain problems. The main objection to the available methods for counting leukocytes is the relatively large error associated with them. This error can be partially compensated for by making duplicate or triplicate counts and using the arithmetic average as representative of the true count.

The direct method of counting the leukocytes suspended in a suitable medium (as Toisson's fluid) in the hemocytometer is useful and satisfactory when one is dealing with normal blood. It is difficult to distinguish pathological immature red

† Expressed in grams per 100 cc.

blood cells from leukocytes by this method. Under these conditions the direct method is obviously subject to error, and other methods are more suitable.

The method of Wiseman (1931) has been found to be fairly satisfactory for the routine study of chicken blood (Olson, 1935; Denington and Lucas, 1955). The modification of Mushett (1956) should be more accurate when the number of heterophils and eosinophils is low. Other methods have also been used (Diesem et al., 1958; Chubb and Rowell, 1959).

The number of thrombocytes may be estimated by counting the number of these cells which appear in the blood smear in conjunction with the 200 or more leukocytes observed in the process of making the differential leukocyte count. From the ratio thus found and the previously found total leukocyte count may be estimated the number of thrombocytes per cubic millimeter of blood.

The coefficients of variation or percentage error have been found in a series of counts of the blood cells to be approximately as follows (using phloxine diluting fluid):

Counts of erythrocytes   5.78 per cent
Counts of thrombocytes .   23.66 per cent
Counts of total leukocytes   34.2 per cent
Differential leukocyte counts:
Lymphocytes ....   8.6 per cent
Heterophils .. .. 27.96 per cent
Eosinophils .. .. .. .58.84 per cent
Basophils ....62.68 per cent
Monocytes ... ... .22.24 per cent

Each worker should determine the order of accuracy that he may expect with a single count of blood cells. The error will be reduced if two complete counts are made and the average of the two used to represent the count. Such a procedure is to be recommended.

Differential counts of the leukocytes and morphological studies of the blood cells may be made from blood smear preparations. Avian blood films should be spread quickly and evenly on clean slides previously heated in an alcohol flame to promote rapid drying. Wright's blood stain may be followed by Giemsa The basic staining elements (especially cell nuclei) of avian blood are much more numerous than those of mammalian blood; therefore, the technique usually employed for staining mammalian blood should be altered in order to obtain the best results with avian blood. No single staining procedure will be satisfactory in all circumstances. Different batches of staining solutions should always be tested by actual use and the staining time varied to suit the individual preparation. In the case of Wright's blood stain the length of time allowed for the stain to act may be varied. The staining time may also be varied with May-Grünwald stain. Giemsa stain may be varied both as to length of staining time and concentration The May-Grünwald and Giemsa combination has been found useful especially with pathological blood as in leukosis when there are many basic staining elements It is also invaluable for staining tissue imprint preparations. In such instances the concentration of the Giemsa solution should be increased.

The number of leukocytes may be expressed in terms of their relative number (percentage value as found in the differential count) or as an absolute number (actual number of cells per unit volume of blood, obtained by multiplying the total leukocyte count by the respective percentage value). The absolute count of the various types of leukocytes is a more reliable index to changes that may occur in an individual animal than the percentage value. A change may occur in the percentage value of one type of cell due to an increase or decrease of another type of leukocyte, although the absolute value of the first type of cell remains the same. For example, given a total count of leukocytes of 20,000 cells and the differential count values of 25 per cent heterophils and 60 per cent lymphocytes, the absolute count would be 5,000 heterophils and 12,000 lymphocytes. Another differ-

ential count might be 12.5 per cent hetero-
phils and 80 per cent lymphocytes, with
a total count of 40,000 leukocytes, which
at a glance might be taken to indicate
a decrease of heterophils by half and a
slight increase of lymphocytes. Actually,
the absolute values of the second count
would be 5,000 heterophils, or no change,
and 32,000 lymphocytes, an increase of
about two and a half times.

For practical purposes, hemoglobin
may be measured by one of the acid hema-
tin methods using a colorimeter or photel-
ometer (Bankowski, 1942). The mano-
metric method remains the most correct
procedure (Rostorfer, 1949).

Erythrocytes and Hemoglobin

The erythrocytes (red blood cells) of
the bird are oval and nucleated. Vari-
ations in shape may be noted in the blood
of a normal bird, and occasionally a spher-
ical erythrocyte may be noted. The
nuclei of the oval cells are likewise oval
and of a mature character. They have
relatively large irregular blocks of deep-
staining chromatin material that is dis-
tinct from the more lightly staining para-
chromatin. The cytoplasm is orange in
color. The round erythrocytes have a
round, slightly less mature nucleus with
smaller clumps of chromatin. Erythrocytes
without nuclei are occasionally seen. The
average dimensions of chicken erythro-
cytes, as found by Scarborough (1931–32)
in his review of the literature, were 12.2μ
by 7.3μ. Lucas and Jamroz (1961) found
their inbred laboratory chickens to have
smaller sized and a greater number of
erythrocytes than commercial stock and
also give data on erythrocytes of other
birds. Jaffe (1960) noted a lower number
of red blood cells, hemoglobin concentra-
tion, and hematocrit value in one of
inbred lines of chickens. The red blood
cells differ in size in different species in
birds, and in general they are larger in
the larger species. Melampy (1918) has
found nuclear material of the chicken
erythrocyte to comprise about one-fourth

the dry weight of the cell and has noted
considerable differences in distribution of
amino acids in cytoplasm and nucleus.
Two components of avian hemoglobin
were distinguished on the basis of amino
acid composition which were different
from any human hemoglobin (Van der
Helm and Huisman, 1958).

The count of erythrocytes and value
for hemoglobin are usually higher in male
birds than in female birds. This difference
does not become apparent until about the
time of sexual maturity. A hormonal in-
fluence is also indicated by the fact that
juvenile and gonadectomized chickens of
both sexes tend to have approximately the
same counts of red blood cells. Domm
and Taber (1946) have shown that
androgens (testosterone propionate) will
cause an increase of erythrocytes in capons
and five-month-old pullets. Younger pul-
lets did not respond as well, indicating
an age factor. Estrogen (alpha-estradiol
benzoate) in large amount tended to
counteract the effect of the androgen.
Large amounts of a synthetic estrogen
caused no change in erythrocytes or various
types of leukocytes of young adult hens
(Diesem et al., 1958). Thyroidectomy of
only male chickens caused a decrease of
erythrocytes, whereas thiouracil treatment
caused a decrease of erythrocytes in males,
females, and capons. The number of
erythrocytes and amount of hemoglobin
vary with the season, the lowest values
being found in the late summer and early
fall, and the highest values in the winter
(Olson, 1937). No seasonal effect was noted
in Hawaii by Tanaka and Rosenberg
(1954), who thought this might be due to
the even temperature of the climate.
Domm and Taber (1946), making obser-
vations at three-month intervals, reported
the lowest erythrocyte values for hens in
the winter and spring coinciding with egg
production. The highest values were ob-
served in the autumn. These workers
noted no seasonal variation of red blood
cells of males or capons. In pigeons and
doves the males have higher values than

the females; the lowest values for hemoglobin and erythrocytes are found in the summer; and the highest hemoglobin levels are noted in the winter, while the largest counts of erythrocytes are noted in the fall (Riddle and Braucher, 1934). A similar seasonal variation has been observed in canaries by Young (1937). Higher blood pressure in the winter than in the summer was noted in both male and female chickens by Weiss *et al.* (1961). This may be a factor related to the seasonal variation of erythrocytes. A 48-hour starvation period was found by Palmer and Biely (1935b) to increase the counts of red blood cells. A diurnal variation of erythrocytes with high values at midnight and low values at noon has been observed (Domm and Taber, 1946). Cook and Harmon (1933) stated that the amount of hemoglobin varied with the intensity of egg production. They did not consider the effect of season, and others (see Olson, 1937) have questioned this statement. Diet will influence the level of hemoglobin, as iron sulfate or casein tend to increase the value (Cook and Harmon, 1933, and Cook, 1937). Hogan and Parrott (1940) found an anemia-preventing factor in the vitamin B complex which later was termed B_c and found identical with folic acid (O'Dell and Hogan, 1943). Deficiency of this vitamin results in anemia, retardation of growth, and reduction of leukocytes and thrombocytes; a larger amount being necessary to maintain a normal level of leukocytes (Campbell *et al.*, 1944). Sturkie (1943) found no significant increase of hemoglobin following asphyxia in either splenectomized and normal hens and thus failed to support the previous report on reservoir function of the spleen by Harmon *et al.* (1932). Pigeons subjected to sudden lowering of environmental air pressure for 8 hours had increased counts of erythrocytes and values for hemoglobin (Kocian, 1936). The factor of indoor versus outdoor environment was found to have no effect on the number of erythrocytes or level of hemoglobin (Olson, 1937).

Measurement of blood cells packed by centrifugation (hematocrit) will provide an approximate index of the number of erythrocytes, and this has been applied in avian hematology. The hematocrit, in conjunction with the number of erythrocytes, is used to calculate the mean corpuscular volume. The hematocrit is not a proper substitute for a count of erythrocytes or a determination of hemoglobin. The color index is computed from these values. Relatively few observations have been made on the fragility of avian erythrocytes.

There are various antigens of the chicken red blood cell. Some can be detected by agglutination of the erythrocytes with bovine serum although specific antiserums prepared in the rabbit permit more detailed study. A comprehensive review of the subject is given by Briles (1960). Each antigen of the erythrocyte is controlled by a gene which belongs to one of seven presently recognized blood group systems. A great number of combinations can occur since all but two blood group loci appear to be located on separate chromosomes. Fanguy (1961) gives a good description of the details of typing.

Polymorphonuclear Heterophilic Granulocytes (Heterophils)

These cells are imperfectly round and have a diameter of approximately 10μ. Their characteristic feature is the presence of many acidophilic crystalline granules in a clear colorless cytoplasm. In the chicken these granules are usually rod- or spindle-shaped. Frequently, in routinely stained smears, especially when Wright's stain is used, these granules are distorted in shape and appear as round or short rod forms. Magath and Higgins (1934) found the granules to be round in the heterophils of the duck. The nucleus is lobulated, with fairly heavy bands connecting the lobes. The number of lobes is usually two or three, and occasionally single or imperfectly lobulated nuclei may be observed. The number of lobes in the

nucleus or Arneth count is sometimes used as a criterion of age of the heterophil. Thus a relatively large number of heterophils with single or few lobes indicates production of many young cells. A relatively large number of heterophils with many lobes indicates aging of the cells with low production of young cells. An impression of the relative number of lobes can be gained while examining a blood smear without actually making an Arneth count. The chromatin and parachromatin arrangement is relatively heavy and coarse in the nucleus. The heterophils function in the defense mechanism against bacterial invasion as phagocytes that can be rapidly mobilized. These cells also have bactericidal action and the power to digest protein.

Male chickens have a slightly higher percentage of heterophils than do females, amounting to approximately 5 per cent. Heterophils also tend to be more numerous in the blood of older birds (Olson, 1937). Considerable variation in the percentage of these cells may occur with the passage of time in a given individual; this variation is somewhat less if one considers the absolute count only. Shaw (1933) reported a diurnal rhythm of the leukocytes of the pigeon. The relative count of lymphocytes is higher than the relative count of heterophils in the morning, but in the afternoon the relative count of heterophils may be greater, equal to, or slightly less than that of the lymphocytes. This is due to an increase in the absolute number of heterophils during the afternoon while the absolute count of lymphocytes remains constant.

Polymorphonucleor Eosinophilic Gronulocytes (Eosinophils)

The eosinophils are of about the same size as the heterophils. They possess relatively large spherical granules whose color is dull red in contrast to those of the heterophil. Magath and Higgins (1934) found the granules of the duck's eosinophil to be rod-shaped. The cytoplasm has a faint bluish-gray tint. The nucleus is often

bilobed, and the chromatin appears to be stained a richer blue than in the heterophil nucleus. The functions of eosinophils are not well understood. It is suspected that they act as a detoxifying power. In some animals and birds they are increased in verminous infestations and are found in the tissues in certain allergic states.

Polymorphonucleor Basophilic Gronulocytes (Basophils)

The basophils are of about the same size and shape as the heterophils. The nucleus is usually masked by the mass of granules in the cells. It is weakly stained, and round or oval in shape, although often it is lobulated. The cytoplasm is clear and colorless. Dark-staining, moderate-sized, basophilic granules are abundant. The material composing the granules is water soluble and may be washed from the cell. More frequently the basophilic material is incompletely washed, and the granules appear distorted and broken up. The function or functions of basophils or their tissue counterpart, the mast cells, are not known despite considerable investigation and many theories. Although there are relatively few basophils in the blood stream of the chicken, tissue mast cells are numerous. It is believed that the tissue mast cell may enter the blood stream and be identical with the basophil, and the reverse, that is, basophils leaving the circulation to become mast cells in the tissues, is considered likely in the chicken.

The number of basophils normally present in the blood is small. A slightly greater number may be found in the blood of young chicks than in the blood of adults.

Lymphocytes

The lymphocytes constitute the majority of leukocytes in the blood of the fowl. There is a wide range in the size and shape of these cells. In the past there has been a tendency to classify lymphocytes on the basis . . . into large, medium, and small

of that individual. These workers (1935b) have also reported that there is an increase of leukocytes amounting to about 25 per cent, after a 48-hour fast. Hoppe (1935) noted a digestive leukocytosis with a maximum number of cells 4 to 5 hours after feeding, but only when the feeding period had been preceded by a 24-hour fast. Cook (1937) states that high counts of leukocytes are commonly found in chickens fed diets in which there is a lack of antihemorrhagic factor or minimal amounts of nitrogenous bases. Brief exposure to high temperatures (15–30 minutes at 112–118° F.) caused a decrease in leukocyte numbers (Chancellor and Glick, 1960).

Thrombocytes

These are the smallest cells seen in the blood of the fowl. They vary considerably in size and form. The typical thrombocyte is oval with a more nearly round nucleus in the center of a clear cytoplasm. There are two or three small, brightly red-staining granules at one pole of the cell. The chromatin of the nucleus is dense and is clumped into relatively coarse masses which are distinctly separated by the parachromatin. The thrombocytes are generally believed to play a part in the coagulation of the blood.

Thrombocytes are slightly more numerous in female than in male adult chickens and also more numerous in young than in adult chickens.

The number of various types of cells and the amounts of hemoglobin in the blood of normal birds are listed in Tables 4.1 and 4.2, representing the values reported in the literature. It is impossible to give a set of meaningful values for blood cells that will fit all circumstances and conditions. Some of the problems involved are discussed in detail by Lucas and Jamroz (1961). The biologist who seeks a normal base line with which to compare his observations should not be discouraged but realize that this is only nature's challenge of his ability to establish adequate and proper controls for his specific experiments.

THE ORIGIN OF BLOOD CELLS

The following discussion of origin of blood cells and relationships in tissues is a generalization. The sources of the information are listed in the references and

lymphocytes. Such a classification is entirely arbitrary as there are no sharply defined distinctions between such groups. The cytoplasm is usually weakly basophilic and may be confined to a narrow rim bordering one side of the nucleus, or it may constitute the major portion of the cell as in the case of the larger lymphocytes. The nucleus is usually round and may be slightly indented at one side. The chromatin pattern is usually rather coarse and blocky, especially in the small, more mature type of cells. In some instances the chromatin is rather fine and is not distinctly separated by the parachromatin material. Occasionally a few nonspecific azure granules may be noted in the cytoplasm especially near the point of indentation of the nucleus. It has been suggested with the support of some evidence that lymphocytes are capable of fixing toxic material and thus acting as a protective mechanism. Due to their high lipase content it has also been suggested that they participate in the digestion of fat. Studies in mammals have indicated that there are more lymphocytes entering the blood stream in 24 hours than are found in the circulation at any one time, which suggests a rather active circulation of these cells from the blood to the tissues and back to the blood again. Lymphocytes are abundant in the wall of the intestine, and many probably pass into the lumen and are lost. Lymphocytes in the tissues may differentiate into various types of cells. Mononuclear leukocytes or polyblasts are found forming a protective barrier between foci of chronic inflammation and healthy tissue. These cells are derived from the blood lymphocyte. It has been demonstrated that the resistance of mice to growth of inoculated cancer cells is directly related to the activity of lymphoid tissue.

The number of lymphocytes in the blood of adult female chickens is slightly greater than in the blood of the adult male chickens. They are also somewhat more numerous in the blood of young birds than that of adult chickens.

Monocytes

The monocytes of the fowl are sometimes difficult to distinguish from the larger lymphocytes, and transitional forms between the two types of cells appear to exist in the blood. Monocytes are large cells with relatively more cytoplasm than the large lymphocytes. The cytoplasm has a blue-gray tint. The nucleus is rather irregular in outline. The nuclear pattern is usually of a more delicate composition than in the lymphocyte, the chromatin having the tendency to appear in the form of strands rather than blocks. The functions of monocytes in the blood are not well understood. It is rather generally accepted that these cells may migrate into inflamed tissues and there hypertrophy to form large active phagocytes. They may then engulf not only bacteria but also particulate matter such as cellular debris; they also have the ability to digest such material. The monocyte is probably capable of differentiation into fibroblasts in the tissues.

Monocytes are more numerous in the blood of adult male chickens than that of adult female chickens. They are also more numerous in the blood of chickens kept in an outdoor environment than that of those confined indoors.

Total Leukocyte Counts

The various factors influencing the number of specific types of leukocytes will obviously affect the total count of these cells. Some such physiological factors have been discussed above and will not be considered here. The total number of leukocytes in the blood is greater in young chickens than in adult birds. Adult chickens kept in an outdoor environment have higher total leukocyte counts than those kept indoors (Olson, 1937). Palmer and Biely (1935d) reported that the counts of leukocytes tended to be high in birds kept in strict confinement. According to Palmer and Biely (1935a), the number of leukocytes in the blood of a chicken tends to fluctuate around a particular level characteristic

FIGURE 4.1

The cells illustrated were selected from dry smear preparations of blood or bone marrow and stained with May-Grünwald and Giemsa combinations unless otherwise indicated. Cells 1 through 12 represent the developmental stages of the erythrocyte. Cells 13 through 27 represent stages of development of the granulocyte. Cells 23 through 46 (except 42) are different types of mature leukocytes. The source of the cells has no special implication except to emphasize the fact that they occur and can be recognized under diverse conditions. For example, cell 3, a lymphoid erythroblast, is not ordinarily found in the circulating blood of lymphocytoma and was probably pushed into the circulation by growth of a focus of the tumor in the marrow.

1. Proerythroblast from marrow, transmissible granuloblastic leukosis. Wright's stain.
2. Lymphoid erythroblast from blood, transmissible erythroblastic leukosis. Wright's stain.
3. Lymphoid erythroblast from blood with leukemoid reaction, spontaneous lymphocytoma.
4. Polychrome erythroblast from blood, spontaneous erythroblastic leukosis.
5, 6, and 7. Polychrome erythrocytes from blood, spontaneous erythroblastic leukosis.
8, 9, 10, and 12. Erythrocytes from blood, normal.
11. Erythrocyte of blood from which nucleus has become lost.
13. Lymphoid stem cell or myeloblast from blood with leukemoid reaction, spontaneous lymphocytoma.
14 and 15. Lymphoid stem cells or myeloblasts from marrow, transmissible granuloblastic leukosis. Wright's stain.
16 and 18. Leukoblasts from blood with leukemoid reaction, spontaneous lymphocytoma.
17. Leukoblasts of Rieder type with lobulated nucleus from blood, transmissible granuloblastic leukosis, Wright's stain.
19 and 20. Metamyelocytes from blood with leukemoid reaction, spontaneous lymphocytoma.
21. Myelocyte from blood with leukemoid reaction, spontaneous lymphocytoma.
22. Myelocyte from blood, spontaneous erythroblastic leukosis.
23. Heterophil granulocyte with variation of granules from blood.
24, 25, 26, and 27. Heterophil granulocytes, normal. Cell 27 shows swelling and rounding of granules as an artifact due to staining reaction.
28, 29, and 30. Eosinophilic granulocytes, normal.
31, 32, and 33. Basophilic granulocytes, normal. Cell 33 shows loss of water-soluble basophilic material from granules.
34, 35, 36, 37, 38, and 39. Lymphocytes, normal.
40 and 41. Thrombocytes, normal.
42. Mitotic figure in immature cell from blood with leukemoid reaction, spontaneous lymphocytoma.
43, 44, 45, and 46. Monocytes, normal.
47 to 54. Plasmodium gallinaceum parasites in erythrocytes of chickens. Blood films through courtesy of the late Dr. F. R. Beaudette.
55 to 59. Haemoproteus parasites in erythrocytes of turkeys. Blood films through courtesy of the late Dr. F. R. Beaudette.

on the twelfth day, confirming the observation of Ackerman and Knouff (1959), the bursa on the fifteenth day with lymphoid cells almost entirely confined to these organs by the eighteenth day of incubation. The spleen was involved almost exclusively in granulopoiesis and liver and bone marrow in erythropoiesis at that time. Soon after hatching, significant lymphoid tissue was noted in the spleen and intestine.

The formation of blood cells in the adult proceeds in a somewhat different manner from that outlined for the embryo. However, in times of stress upon the hematopoietic system or in some primary pathological conditions, there may be a partial return to the embryonic type of hematopoiesis. Erythrocytes and granulocytes are formed principally in the bone marrow. The erythrocytes are developed within sinuses lined by endothelial cells. Under normal conditions the young and immature erythrocytes are held within the sinuses during their development. When mature they are released to the circulation. Evidence indicates that the sinuses are in open communication with the blood circulation; however, the mechanism by which the immature cells are retained within the sinuses until maturity is not known. Granulocytes are formed principally in the bone marrow. Their locus of development is in the intersinusoidal areas and, therefore, extravascular. Under normal conditions they usually develop by multiplication of leukoblasts and premyelocytes, cell types already partially differentiated and fixed in their line of development. When the granulocytes have matured sufficiently they enter the circulation by migration into adjacent sinusoids. The myeloblast or hemocytoblast represents an ancestral cell type common to both granulocytes and erythrocytes. These cells occur in the marrow and according to Jordan (1936) are represented by the germinal cells in the lymphoid nodules. His work indicates that the germinal cells produce small lymphocytes which surround them as a mantle. The lymphoid hemoblasts in the marrow may become either

granulocytes or erythrocytes, depending on whether or not they gain access to the sinusoids before undergoing further development. The lymphoid hemoblasts or small lymphocytes may also form thromboblasts which multiply in the sinusoids and later become thrombocytes. Jordan and Robeson (1942) believe the spleen is a normal source of the small lymphocytes in young pigeons. They demonstrated development of lymphoid foci in the marrow similar to those of the spleen as a result of splenectomy. This increase of lymphoid tissue supplied the deficiency resulting from loss of the spleen.

The source of blood lymphocytes is chiefly the diffuse lymphoid tissue scattered along the intestinal tract, in the liver, and in the spleen, together with the more or less organized nodular lymphoid tissue of the spleen, thymus, cecums, and palatine tonsils. Jordan (1936) believes that the small lymphocyte or the bone marrow (lymphoid hemoblast) is identical with that of the circulating blood. The circulating lymphocyte of the blood may then be regarded as a potential hemoblast. Likewise, the germinal center cells in the organized nodular lymphoid tissue are hemocytoblasts.

THE RELATIONSHIPS OF BLOOD CELLS IN THE TISSUES

A consideration of the blood cells in the tissues leads to one of the most fascinating aspects of hematology, as well as to one of the most confusing. With the exception of the erythrocytes, all cells of the blood have important functions in the tissues outside of the blood stream under normal as well as pathological conditions. Such cells as the heterophils fulfil their function in the tissues without change. The mononuclear leukocytes (lymphocytes and monocytes) are endowed with the ability of transformation into other types of cells in the tissues. Studies of such transformations have been made by various means. Morphology alone is a useful and important method of study, but it does not indicate function as well as does physiological study by

means of tissue culture methods, supravital and intravital staining, and observations on the property of phagocytosis. The tissue cells of mammals have been studied more extensively than those of birds; however, it has been shown that analogous cell types exist in the chicken. This discussion is, therefore, rather general in nature.

Aschoff grouped an extensive and widespread system of phagocytic cells under the term reticulo-endothelium. The elements of this system are most numerous in the blood-forming organs. The cells belonging to this system have been given various names (fixed and free macrophages, clasmatocytes, Kupffer cells, active and resting wandering cells, histoblasts, littoral cells, histiocytes, adventitial cells, alveolar phagocytes of the lung, and others). Mann and Higgins (1938) suggest the use of the term histiocyte to designate the cells of this system. Thus there are the fixed histiocytes representing that portion of the system which lines the vascular sinusoids, such as the littoral cells of the liver, spleen, organized lymphoid tissue, and bone marrow. The free histiocytes include those elements of the reticulo-endothelial system found free in the tissues. The cells of the reticulo-endothelial system, the blood cells, and the fibroblastic cells have a common origin from the mesenchyme. Under many conditions they react as a group to protect the body from injury. The reticulo-endothelial system is in addition associated with the metabolism of iron, lipids, carbohydrates, and proteins, and the destruction of red blood cells as well as other processes of the body.

The free histiocytes of the tissues have many morphological variations. The term polyblast was suggested by Maximow as descriptive of the histiocytes observed in areas of inflammation. The free histiocytes are regarded as being derived principally from the lymphocytes and monocytes of the blood. Some may be formed by cell division of histiocytes and others by differentiation of fibroblastic elements. Some fixed histiocytes may become free and active. Transitional forms of histiocytes resembling fibroblasts are found in the tissues, suggesting the development of such cells into fibroblasts or the reverse. Both processes have been observed in tissue cultures. It should be pointed out that tissue cultures of fibroblasts indicate the existence of different races and that the physiological properties and developmental tendency of such cells depend upon their origin and environment.

The fixed histiocytes are numerous in the sinusoids of the liver and spleen of the chicken where they actively phagocytize foreign particulate material. They exist in the lung as alveolar phagocytes, in the central nervous system as microglia, and in the loose connective tissue as sessile cells attached to the connective tissue fibrils. The fixed histiocytes may occur in any organ in the form of adventitial cells, in the adventitia of small blood vessels, and about the capillaries.

There is considerable variation in the amount of lymphoid tissue in the organs of normal chickens. The thymus and bursa of Fabricius increase rapidly in size after hatching of the chick and retrogress by the time of sexual maturity. Glick (1956) found that the bursa reached maximum size at four and one-half to six weeks in White Leghorn and ten to twelve weeks in Barred cross chickens. Cortisone (Glick, 1959), ACTH, and stress (Morita and Nishida, 1956; Newcomer and Connally, 1960) caused a decrease in size of the bursa of Fabricius. The lymphoid tissue in the spleen, wall of the intestine, and periportal areas of the liver varies in amount. Thorbecke et al. (1957) reviewed the literature on distribution of lymphoid tissue and found less development of lymphoid tissue in germ-free chickens. Mural lymphoid nodules (0.1 to 2.5 mm.) located at irregular intervals along lymph vessels and particularly abundant in the legs are described by Biggs (1957). A procedure for staining the dissected lymph vessels was required to locate the nodules. Myeloid metaplasia is a term usually used to indicate the formation of granulocytes in

organs other than the bone marrow. Such myeloid metaplasia may sometimes be observed in the lymphoid tissue of the thymus, periportal areas of the liver, and wall of the intestine. Huff and Bloom (1935) found marked extramedullary granulopoiesis and erythropoiesis in the spleen, liver, and kidney of canaries affected with malaria. The factors which control the amount of lymphoid tissue and degree of myeloid metaplasia are not well understood. In general it appears that age is one controlling element, as the lymphoid tissue is less active in older birds.

The role of the thymus, bursa of Fabricius, and spleen in development of immunity has attracted much attention in the past few years. Simonsen (1957) demonstrated that cells from the blood or spleen of a chicken mature enough to produce antibodies can be transplanted to the spleen of an embryo where they will grow and produce antibodies against their host. This results in a severe hemolytic anemia usually fatal in the second or third week after hatching. This is the reverse situation from actively acquired immunological tolerance in which the host cannot produce antibodies against foreign homologous cells when the host was exposed to these foreign cells in embryonal or neonatal life (Billingham et al., 1954). Bursectomized chickens have a reduced ability to produce antibodies (Glick et al., 1956; Mueller et al., 1962). Chicks hatched from eggs treated with 19 nortestosterone on the fifth or twelfth day of incubation have no bursa of Fabricius, a reduced thymus and spleen, and form antibodies poorly (Mueller et al., 1962). Hilgard et al. (1962), measuring the tolerance by graft of lymphocytes on chorioallantoic membranes, found that the tolerance decreases rapidly with age in most chickens but may last indefinitely in some. The chick with no bursa had little resistance to injection of adult homologous spleen cells which grew markedly in the spleen, peritoneal cavity, and subcutis (Papermaster et al., 1962). Because of the sequence of lymphoid development, Paper-

master and Good (1962) suggest that immunologically competent lymphoid cells may arise in the bursa and thymus, then populate the spleen, bone marrow, and other sites. Szenberg and Warner (1962) used three tests of immunological competence of chicks treated with testosterone in embryonal life. Some of the chicks had no bursa but would still reject a skin graft. Others had no bursa and complete atrophy of thymus cortex and would accept homologous skin graft. Both groups did not produce a circulating antibody or show delayed hypersensitivity to tuberculin. They concluded that the bursa is primarily responsible for production of a circulating antibody and delayed hypersensitivity, and the thymus is involved in host reaction to skin graft.

THE BLOOD IN DISEASE

Anemia is a condition in which the blood is deficient in either the number of erythrocytes or the amount of hemoglobin or both. The term is also sometimes applied when the erythrocytes show abnormal morphological features. Anemia may be associated with either acute or chronic disease, due either to suppression of blood cell production or to toxic destruction of blood cells. It may follow the loss of blood. Wirth and Kubasta (1939) have demonstrated the regenerative ability of the blood-forming tissues of the normal chicken by removing up to 85 per cent of the blood and observing the return of erythrocytes to normal levels within eight to nine days. The blood-forming organs of birds affected with disease will not respond with such rapidity. Anemia may result from the lack of constituents necessary for blood cell production, as in dietary deficiencies. The erythrocytes in anemia may show morphological deviations from the normal. The individual cells may be either larger or smaller than normal (anisocytosis). They may assume a variety of shapes such as being pointed at one end, or round (poikilocytosis). Immature erythrocytes may be found in large numbers in the blood, depending upon the

rate of production in the marrow. Many such immature cells are deficient in hemoglobin as indicated by the color of the cytoplasm which is blue-gray-yellow (polychromasia). It is important to distinguish between the blood picture of a severe regenerative anemia and that observed in erythroblastic leukosis. In the latter instance one may usually find the progenitors of the erythrocyte (lymphoid cells and lymphoid erythroblasts) in the blood. These are not usually present in the blood in simple anemia. Ishiguro (1957) has described a transmissible anemia which might be an anemic form of erythroleukosis. Study of bone marrow would aid in such a situation.

Leukocytosis is an increase in the number of leukocytes in the blood. Leukopenia is a decrease in the number of leukocytes in the blood. As has been mentioned, there is considerable variation in the number of leukocytes in the blood of normal chickens. In many disease conditions, especially bacterial infections, there may be a leukocytosis. Various irritants may act in different ways. Some may attract a specific type of cell and repel others. Some toxic materials may stimulate the blood-forming tissues to production of nearly all types of leukocytes. Others may suppress the production of leukocytes and lead to a condition of leukopenia. Myelocytes containing preacidophilic granules that take a basic stain are described as occurring normally in the blood of the ostrich (Jackson, 1936). In marked heterophilic leukocytosis there may be myelocytes in the peripheral blood. Such a condition should not be mistaken for leukemia as it merely represents the tremendous effort on the part of the bone marrow to fulfil the demand for heterophils that do not have time to ripen before being pushed into the blood stream.

Anemia and leukocytosis may accompany many bacterial diseases. The study of the blood picture cannot be relied upon to serve as a differential diagnostic test in the group of infectious bacterial diseases. The increase should be regarded as an index of the response of the defense mechanism of the host against the infection. A study of the blood and blood-forming tissues is essential for the diagnosis and differentiation of leukosis from other diseases of the fowl. Infections with Salmonella species of bacteria provoke a marked heterophilic leukocytosis in chickens (Moore, 1895–96; Taylor, 1916; Cook and Dearstyne, 1934; Olson and Goethius, 1937; and Wai and Stafseth, 1950). Anemia also is commonly present in such bacterial infections. Gauger et al. (1940) found no difference between the counts of erythrocytes and leukocytes in the blood of pigeons that were positive to a serological test for paratyphoid infection and those that were negative. Buxton (1960) has observed a severe hemolytic anemia in the last three days of acute, fatal fowl typhoid which appears to be due to sensitization of erythrocytes with bacterial polysaccharide and increased activity of the reticulo-endothelial system. In chronic fowl typhoid, the hemoglobin is decreased but not to such low levels. Ward (1904) has reported anemia and increased numbers of leukocytes in chickens with fowl cholera. Chickens spontaneously affected with tubercolosis have been found to have anemia and a leukocytosis of heterophils and monocytes (Olson and Feldman, 1936). Grimal (1938) studied the blood in two experimentally produced cases of the acute (Yersin) type of tuberculosis. A relative leukocytosis of lymphocytes was noted in the first week and of monocytes in the second, with a terminal relative leukocytosis of heterophils. These birds died 23 and 25 days after inoculation. Pomeroy and Fenstermacher (1937) described the findings in the blood of two turkeys with hemorrhagic enteritis. They observed anemia in both and a heterophilic leukocytosis in one. Wannop (1961) observed a decrease of erythrocytes and an increase of heterophils and monocytes in turkeys with "X" disease but commented that the same changes had been noted in other diseases of turkeys. Seastone (1935) observed a marked

monocytosis in chickens with experimentally produced listeriosis. Following intravenous inoculation of the bacteria, the monocytes increased from about 5,000 per mm.^{3} to a peak of 60,000 per mm.^{3} in five days, and at eight days dropped to about 10,000 per mm.^{3} There was only a moderate increase of granulocytes and apparently no disturbance of the lymphocytes.

Hemoglobin, erythrocyte, and leukocyte (total and relative values) measurements were essentially similar in experimental infectious synovitis whether caused by an agent or by pleuropneumonia-like organisms (Olson et al., 1957). There was anemia. The leukocytes increased from twenty to eighty thousand in 12 days and remained so for about 33 days. The absolute values were not given but there appeared to be an increase of heterophils, immature cells, and monocytes with perhaps a moderate increase of lymphocytes.

Thorp and Graham (1932) reported the results of counts of erythrocytes and leukocytes made on the blood of 71 chickens affected with acute laryngotracheitis. They found the number of erythrocytes to be within normal limits and the number of leukocytes to be slightly lower than the normal values for these cells as reported by other workers. It is pertinent to note that Thorp and Graham (1932) used the Blain method for counting leukocytes. This method has been observed to have a tendency to produce lower counts of leukocytes than other methods. In some cases of Newcastle disease, DeKoch (1954) observed a monocytosis and reduction of small lymphocytes. Many of the circulating monocytes contained phagocytosed red cells. The bone marrow was not affected, but degeneration and depletion of lymphocytes and an increase of reticulum cells and plasma cells were marked in the lymphoid deposits of the spleen, liver, and intestinal tract. Fredrickson and Chute (1958) noted a decrease of all leukocytes on the eleventh day of Newcastle infection and an increase of monocytes and heterophils on the fourteenth day. The sedimentation rate, plasma specific gravity,

and values for buffy coat were also altered during the disease. Sharma and Seetharaman (1950) observed anemia, a slight heterophil leukocytosis, and lymphopenia (to a calculated one-third pre-exposure level) in adult chickens 3 and 4 days after infection with Ranikhet virus.

An increase of eosinophils has been noted in the blood of a chicken with coccidiosis and tapeworms (Yakimoff and Rastégaieff, 1929), in a grouse harboring Trichostrongylus pergracilis (Fantham, 1912), and in chickens with Capillaria columbae infection (Olson and Levine, 1939). A leukocytosis of heterophils and slight anemia were also noted in Capillaria columbae infection. Chickens with coccidiosis have been observed to have a relative heterophilic leukocytosis (Fantham, 1912) and an increase in the total number of leukocytes (Krömker, 1937). A controlled infection of chickens with Heterakis gallinae demonstrated an increase of heterophils and eosinophils, though the increase was not related to the number of parasites present (Wickware, 1947). Experimentally produced and natural cases of typhlohepatitis (Histomonas meleagridis infection) in turkeys were found by Johnson and Lange (1939) to be associated with a relative heterophilia and monocytosis. Except for a slight anemia of uncertain significance, no changes of the blood were observed by Olson (1935) in chickens before and after treatment for heavy infestations of lice. Yakimoff and Rastégaieff (1930) have noted a decrease in the percentage of lymphocytes and an increase in heterophils together with a slight relative decrease in monocytes in chickens experimentally afflicted with spirochetosis. They also have observed a heterophilic leukocytosis in two spontaneous cases of spirochetosis. Coles (1939) states that a marked anemia may occur in young chicks with aegyptianellosis, but that the infection in adult birds is associated with only a transient anemia. Jacobi (1939) found that the number of erythrocytes dropped to about one-third the normal level during the acute stage of experimental infection

with *Plasmodium gallinaceum;* later the erythrocytes and hemoglobin were slowly and simultaneously regenerated to their normal levels. Rostorfer and Rigdon (1946) have shown the anemia of ducks with experimental acute malaria to be of the macrocytic hypochromic type. There was also a decrease in functional hemoglobin in relation to the hemoglobin measured as acid hematin.

Krömker (1937) reported anemia to be associated with gout. He also studied the blood of a chicken with fowl pox and found an increase in the total number of leukocytes at the time the skin lesions were beginning to dry.

The work of Goff et al. (1953) suggests that a heterophil leukocytosis, increased hematocrit and mean corpuscular volume with decreased corpuscular hemoglobin may be used to diagnose an early or borderline deficiency of riboflavin in young chickens. These changes returned to normal when riboflavin was supplied or after birds reached 12 weeks of age. Urethane, X-ray, and aminopterin decreased the number of circulating leukocytes (Dinning et al., 1950).

Vitamin K is related to clotting of the blood, and Griminger and co-workers (1953) found that it would reduce the clotting time prolonged by terramycin, arsenic, and arsanilic acid. Gray et al., (1954) studied the blood in 20 cases of hemorrhagic disease, in which growing chickens died with hemorrhages principally in skeletal and cardiac muscles, subcutis, and intestine. The clotting time was prolonged and the thrombocytes were enlarged and vacuolated. The number of heterophils varied but anemia was quite constant. The marrow was aplastic and a leukopenia existed near the time of death. Essentially similar findings in a larger number of cases were reported by Cover et al. (1955), who differentiated the condition from vitamin K deficiency. The aplastic anemia problem continues to exist with no new knowledge of its etiology (Hanley, 1962).

Increased coagulation time of blood and

decrease in erythrocytes were noted in birds with avian encephalomyelitis and/or fed sulfaquinoxaline (Morrissette et al., 1959).

Poisoning from the ingestion of lead causes anemia in wild ducks with basophilic stippling of the erythrocytes, according to the findings of Johns (1934). The question of whether or not basophilic stippling of erythrocytes occurs in lead intoxication in chickens is not settled. Key (1924) cites Minot, and Meyer and Speroni to the effect that there is no stippling. Veenendaal (1935) reports having observed anemia without basophilic stippling in chickens with lead poisoning.

Lührs (1936) has described the changes in the blood of pigeons after exposure to high concentrations of war gases (phosgene and mustard). These changes were a relative increase in heterophils and a decrease in lymphocytes. The value for hemoglobin was low immediately preceding death of pigeons exposed to mustard gas. No characteristic degenerative changes of the blood cells were observed.

Under some circumstances of infection or disseminated neoplastic disease there may be a pouring out of unripe blood cells into the blood circulation. This leukemoid reaction may be so marked as to resemble a state of true leukosis. Sometimes there is sufficient evidence of granulomatous or metastatic neoplastic growth in the marrow to explain the reaction by a crowding out of the normal hematopoietic elements

Marked changes occur in the bone marrow and peripheral blood in fowl leukosis. This disease and lymphocytoma are discussed in detail in another section to which the reader is referred for a discussion of the hematology of these diseases.

The functions of the cells of the blood are of such a nature as to make them of great significance in both health and disease. Information on variations of chemical constituents of the blood is accumulating (Sturkie, 1954), and this can be correlated with our information on cells. Knowledge of the changes of the blood and blood-forming organs should consti-

tute an important part of our information on diseases of birds. Such knowledge should consist of more than mere "counts" of the blood cells and should embrace facts concerning the qualitative changes of cells such as indications of degeneration or regeneration of blood cells in the blood and

tissues. Studies should be made at different stages of disease and the changes correlated with the course of the disease. Constant additions to our information are being made in the literature of today and should lead to better understanding of avian hematology in the future.

5

Principles of Disease Prevention

The trend in all agricultural industries is towards larger units, fewer farmers, and corporate operation. Poultry and turkey industries have been following these trends, and with them have come stress on efficiency of operation and lower cost of production. In the chicken industry, larger laying flocks, a shift to cage layer operation, and mass rearing of broilers are examples. For a number of years turkey flocks have been increasing in size with many small part-time raisers leaving the business. Corporation farming and the tendency towards integration of breeder, hatchery, brooding, rearing, and feed supply operations under one management present new and different problems in all types of management.

The cardinal principles of disease prevention and control, however, have not changed. It will not be the purpose of this chapter to give details on methods adapted to modern trends but only to attempt to outline fundamentals that can be applied to all phases of the industries. The reader

is referred to individual chapters on specific diseases for specific information concerning them. It is also emphasized that to keep abreast with the enormous research now under way, the reader must supplement what is given herein by a constant survey of the current literature. It will be especially important to be on the alert for new information which will be forthcoming as a result of the increased interest in environmental research. Standard textbooks on poultry and turkey production are other sources of information. Examples are Card (1961) and Marsden and Martin (1955).

The same principles of disease prevention apply to poultry as to other livestock; and they are, to a large extent, the same as those applying to human beings. Van Es and Olney (1934) summarize the factors conducive to health and body efficiency: "(1) soundness of body and of constitution and vigor, (2) adequate nutrition, (3) suitable environment, and (4) eradication and control of transmissible

diseases." Although immunity to disease cannot be guaranteed when poultry is reared according to these principles, the grower who observes them will increase his chances of raising a profitable flock.

SOUNDNESS OF BODY AND CONSTITUTION

The most important factor in having a flock of sound, vigorous birds that have good constitutions is the breeding history of the flock. Selection of healthy, well-matured stock will aid in developing a disease-free flock. The ancestry of the breeding stock should be considered; birds from a parent that had some genetic defect, such as a pendulous crop, crooked toes, or a curved spine, should always be avoided. A chick or poult that has come through the season without such a setback will serve much better for propagation than the one that has had several setbacks Before being finally selected as a breeder, each individual should be examined for defects and discarded if abnormal in any way. When buying hatching eggs or day-old chicks or poults, one should demand stock from disease-free breeding flocks that meet the requirements just discussed.

ADEQUATE NUTRITION

An adequate diet supplies all the essentials for normal growth. With any one essential ingredient lacking, or in improper balance, normal development will be retarded. A diseased condition directly or indirectly due to the faulty ration may result. Whether or not many birds die in such cases, slow development may cause as great a monetary loss as if there had been severe mortality. Some of the dietary disorders will be discussed in Chapters 6 and 7.

SUITABLE ENVIRONMENT

The term "environment" refers to the surroundings in which the birds must live Necessarily, this environment varies with the methods of rearing. The obsolete practice of hatching and rearing with hens is an example of an entirely different type of environment from that furnished by the modern method of incubator hatching of eggs and brooder rearing of young birds. Furthermore, the range rearing of poults or chicks is in contrast to the confinement method. In any case, the relation to disease depends on the ability of the environment to aid nature in combatting disease. Dryness, drainage, amount of sunshine, nearness to other species of fowl or other animals on the same premises, location in respect to other farms, type of soil, and shelter facilities are examples of environmental factors that may influence the disease problem.

ERADICATION AND CONTROL OF TRANSMISSIBLE DISEASES

Transmissible diseases, once established, may cause heavy losses. Examples are histomoniasis (blackhead), hexamitiasis, fowl typhoid, fowl cholera, pullorum disease, salmonellosis (paratyphoid), infectious bronchitis, Newcastle disease, chronic respiratory disease (CRD), laryngotracheitis, fowl pox, and coccidiosis. The two general ways of introducing infectious diseases into a flock are by natural and mechanical carriers.

Natural Carriers

The most serious carriers of infections are birds or other animals which have apparently recovered from the disease in question but which still retain the infectious organisms in some part of the body where they continue to multiply and to be eliminated. Among the diseases known to be transmitted by carriers are histomoniasis, hexamitiasis, Leucocytozoon infection, coccidiosis, fowl typhoid, pullorum disease, salmonellosis, tuberculosis, fowl cholera, and many respiratory diseases. Removing carriers from the flock and premises is an effective way of preventing a recurrence of an outbreak. Different methods of accomplishing this end exist; *but one, common to all diseases, is absolute isolation of the adult breeding flock from the growing flock.*

The depopulation method is most ap-

plicable to newly introduced diseases and especially to exotic diseases like fowl plague. It may also be used to rid the premises of diseases such as *tuberculosis*, fowl cholera, fowl typhoid, and infectious laryngotracheitis. Depopulation, as well as other phases of disease eradication, is a community problem and one must have the cooperation of all poultrymen if success is to be insured. The time between depopulation and purchase of disease-free day-old replacement stock will depend on many factors discussed under the diseases in question. Environment plays an important part in the time interval necessary to insure success.

It is extremely important that *all* replacements for any system of management come as pullorum-typhoid-disease free (U.S. Pullorum-Typhoid-Clean) eggs, chicks, or poults. *The purchase of started chicks or poults is an excellent means of introducing many diseases into a flock.* Such diseases as Newcastle disease, coccidiosis, and the various respiratory diseases are especially prone to be spread by purchase of chicks that have been reared from a few days to a few weeks by the hatchery.

The purchase of adult birds for breeding flock replacements is another common way of introducing disease into a flock. All breeding flock owners should therefore always purchase their replacements as hatching eggs or day-old chicks or poults and only from known disease-free sources.

An equal chance is taken by the breeding flock owner who exhibits his breeders at shows or fairs and then returns them to his ranch. If he must show his birds, he should select individuals which can be sold for market purposes after the exhibition is over. Fowl pox, respiratory diseases, and external parasites are likely to be the price paid for returning birds to the home farm following their exhibition at shows. Egg-laying contests fall in the same category as fairs and shows. The increase of cage layer flocks has created an interest in "started pullet" supplier businesses to sell started pullets to cage layer flock owners. This system of obtaining replacements has many advantages, but it can be a dangerous practice as far as disease control is concerned. The system is conducive to the spread of disease and must be very carefully controlled to prevent introduction of new diseases into a flock.

Unfortunately, carriers of the more common diseases of poultry cannot be detected by simplified tests that are practicable. The agglutination tests for carriers of fowl typhoid, for pullorum disease, a few of the other salmonelloses (paratyphoid) and chronic respiratory disease are exceptions. Strict supervision over all supply flocks will help to secure eggs of the best quality.

Chickens may be carriers of many diseases common to both turkeys and chickens. It is equally true that turkeys may be carriers of diseases which may cause severe losses in chickens. Turkeys and chickens can be reared as pen mates or in adjoining yards, provided both species are free from disease; but the chances that chickens may carry blackhead or other diseases or that turkeys may carry chicken diseases are too great to risk (Fig. 5.1). Wild birds, such as quail, pheasants, pigeons, and sparrows, are susceptible to many of the diseases of chickens and turkeys, such as salmonellosis, blackhead, hexamitiasis, respiratory disease, and fowl cholera. Psittacine birds as well as certain wild waterfowl must be considered possible carriers of ornithosis (psittacosis) to turkeys, chickens, and ducks.

Mechanical Carriers

Mechanical carriers include all means by which infectious organisms are accidentally carried from place to place: man, animals, wild birds, insects, dust storms, moving vehicles, feed sacks, poultry crates, and flowing streams.

Man is the worst offender, and the attendant who cares for both an adult and growing flock may be the principal carrier to the young flock. It has been shown that a person may carry viable coccidial oocysts on his shoes for several hours and be responsible for contaminating clean feed in

FIG. 5.1 — Chickens and turkeys should not be reared in the same yard.

the process of mixing it. It has also been proved that coccidial oocysts may remain on the soles of shoes after the wearer has walked for at least one-half mile, and, when washed from the soles, are capable of producing fatal cases of the disease. Thus, if adult turkeys or chickens are to be kept on the same premises with poults or chicks, great care must be taken to prevent spread of the disease from the adults to the young by attendants. This precaution applies also to other diseases.

Visitors, especially other poultry growers, feed salesmen, and service men, are the principal offenders aside from the attendant himself. The poultry grower should avoid visiting neighboring farms if disease is known to be present. Visitors should be cautioned about entering the houses and yards. The feed dealer's or the poultry buyer's truck and the borrowed spray tank that has been making the rounds of the farms may be sources of disease. The used feed sack, the poultry crate that has not been thoroughly cleaned and disinfected after being sent to market, and the hoe or scraper that is used in the pens of the brooder house carriers and then in the brooder house without being cleaned, are other possible sources of disease. The use of paper feed

sacks that can be discarded eliminates the secondhand feed sack problem. Jungherr (1950) has reviewed the literature, and reported his attempts to sanitize used feed bags. He was not successful in finding a satisfactory practical method. The modern tendency towards bulk storage and bulk handling of feed has probably aided in prevention of disease by reduction of the chances of contact with contaminated objects, as well as aiding to eliminate the used feed bag problem.

Since carcasses from diseased birds, offal, and feathers can be classed as possible sources of disease, such material should be burned or buried deep. Contaminated soil, and water polluted by dead birds thrown into streams even at some distance from the premises, are other sources.

Hospitals and hospital yards may be important in spreading disease to different pens or houses on a ranch. Sick birds from several pens congregated in one hospital pen or house and later taken back to their respective quarters may not only carry back the condition for which they were removed but one or more diseases contracted while in the hospital. For this reason hospital pens are not advocated.

Passerine birds, dogs, cats, rodents, and
FIG. 5.2 — Wire sun porches are an aid in preventing disease. This shows an example of a sanitary runway attached to the front of a portable brooder house. (Payne, Kans. Agr. Exper. Sta.)

insects are difficult to incriminate as mechanical carriers, but they are possibilities and should be kept away whenever possible.

SANITATION

Sanitation may be defined as the means and measures directed toward establishing and maintaining an environment in which it is safe for animals to exist. The factors considered on the preceding pages are important adjuncts to any sanitary program. Especially important is the elimination of carriers. Other factors to consider are houses, yards, water supplies, and food.

Houses and Yards

The first step in the sanitation of brooder houses is the original construction. Ease of cleaning and disinfection, proper isolation of each unit in the case of the multiple-pen type, separate entrances for each unit, sanitary water and feeding systems, and rodent-proof feed storage containers should be considered when building a brooder house. Facilities for cleaning the individual houses and yards can be arranged by having a gate in the front entrance of each yard.

Wire sun porches and wire platforms

are an aid in preventing disease (Fig. 5.2). It is important that the wire used for sun porches and platforms be heavy enough to hold birds without sagging and that the mesh be of sufficient size to permit droppings to fall through readily. A mesh 1″ x 1″ or 1″ x 1½″ will serve best for all purposes. Even for very young chicks and poults it is seldom necessary to use less than a ½″ x ½″ mesh wire.

The number of birds on a given area, either in the brooder house or on the range, may influence the livability. Overcrowding means more work in keeping the surroundings clean and dry; it also increases the problem of feeding and ventilation. These factors indirectly lower the resistance of birds and facilitate spread of disease. There are many factors to be considered in determining what constitutes overcrowding, but use of common sense by the grower will answer most of the questions as to the number of birds to be housed under various local conditions.

The reader is referred to standard textbooks, current experiment station bulletins, and reliable journals for detailed information on space requirements for chickens and turkeys of various ages.

Yards or ranges should be maintained

free from all infections and infestations. Chickens should never be reared in yards with turkeys. For the confinement method of rearing turkeys, rotation of runs is recommended. In large range areas, rotation of runs is impossible; but feeding grounds and feeding areas can be moved at least twice a week as an aid in preventing accumulations of manure and litter, wherein lies the greatest danger of disease. Good drainage that prevents the formation of stagnant pools in yards is necessary. The probability of introducing disease is directly related to the amount of parasitic invasion. If moisture is not present, only the more resistant organisms can remain alive and infective. Good drainage, such as is found on sandy or gravelly soil, aids in keeping infections at a minimum because of the dilution factor of rains. Dry, hot regions having an abundance of sunshine aid in reducing the possibility of contamination and therefore in preventing disease. The range method, which provides enough ground so that birds can be moved frequently to clean areas, likewise helps.

Water Supply

Since the water supply is no better than the poorest water available, all sources other than those known to be clean and safe from contamination should be removed. The best type of water fountain is of no value in preventing disease if it is allowed to overflow and to form a stagnant pool. The immediate area around the permanent fountain or drinking place should be filled in for several inches with gravel, or the container should be set on a screened platform with a mesh $1'' \times 1''$ or $1'' \times 1\frac{1}{2}''$ to insure a dry area, which will help to prevent the spread of disease. In houses or in yards, wherever possible, an automatic watering system with proper drainage for disposal of the surplus is recommended. Figure 5.3A and B illustrates types of watering devices that are recommended. Many other types of ready-made sanitary water equipment are on the market.

For young birds, from 15 to 20 one-gal-

lon fountains for each 1,000 birds are recommended. Older birds should have from 48 inches to 72 inches of water fountain space accessible on both sides per 1,000 individuals. The number and capacity will vary with conditions, and growers should make sure that there are ample supplies to keep water before the birds at all times.

When automatic systems are used, they should be inspected frequently to insure that they are operating properly. It is especially important to check the pressure systems that are equipped with automatic drug-dispensing devices. Pure, fresh, clean water is the most palatable. If well protected from contamination by body wastes, soil, and feed, it far surpasses the same water which has been medicated for decontamination purposes. Birds do not like most of the drugs recommended for drinking water; often they avoid water because of this dislike. With the continuing increase of use of antibiotics and other drugs as additives to feed and/or water for specific disease control, precautions must be taken to prevent excessive use of them and to insure that the quantities added are in amounts that will be readily accepted by the birds.

Streams and irrigation ditches as a source of water are safe provided they come from uncontaminated sources, are not stagnant, and are flowing at a fair rate of speed. *Pools of stagnant water from overflowing or leaking canals or water from ditches that are not flowing cannot be considered reliable.* Since poisoning from salt water and alkali water has been reported, it may be desirable to have water suspected of having caused poisoning analyzed by a chemist.

Feeds and Feeding Methods

Feed as a mechanical means of carrying infection has already been mentioned. In addition, feed may directly transmit fungus diseases, botulism, and possibly other infections. For these reasons, one should purchase the best feed and protect it from dampness and from all sources of infection. *Moldy feed should never be given.*
FIG. 5.3 — (A) Two types of commercially made galvanized waterers suitable for poultry. These should be set on wire platforms to insure dry surroundings. (B) "Van Es" type of water fountain. It provides for a continuous flow of water in the bubbler and for passage of overflow into the tile drain. The drinking cup is placed 8 inches above the ground, is kept automatically cleansed, and can be regarded as strictly sanitary. (Van Es, Univ. of Nebr.)

Several outbreaks of mycosis originating from contaminated milk containers have been observed by the author. Failure to wash and scald daily the cans used for transporting milk from the dairy to the range was the most common cause. Improper care of semisolid milk may be another source of mycosis. Forgacs et al. (1962) showed that under some conditions feed contaminated with any one of several species of molds may cause a marked hemorrhagic disease of chickens.

Safeguarding the feed against fecal matter and other refuse by using properly constructed feed hoppers is a necessary procedure in the sanitary program. There are three general types of feeders in common use on poultry farms. These are (1) the mechanical feeder, (2) the trough type, (3) the hanging type. A hanging and trough type are illustrated in Fig. 5.4 A and B. The proper use of any of these types is essential. It is especially important to keep them adjusted properly for the
FIG. 5.5 — The type of surroundings that invites rat and mouse invasion and in turn increases disease transmission possibilities.
FIG. 5.6 — This modern house has many features which aid in disease prevention. They include outside feed storage tanks, roof ventilation (evaporator coolers), and two large doors on either end to facilitate cleaning between lots. (Pacific Poultryman.)
FIG. 5.7—Type of wire platform used at the Los Angeles County (California) Poultry Demonstration Plant, for feeders and waterers. Note the length, width, height, and the size of the wire mesh (1" x 1½"). (Hinshaw, Univ. of Calif. Agr. Exper. Sta., Bul. 613.)

pends on the nature of the environment, the character of the infectious agent to be destroyed, and the method to be used.

Cleaning, before the final application of chemicals, is essential in any disinfection program; cleaning alone will not result in disinfection, but, if carried out properly, it will render disinfection by chemicals more efficient. The following steps are suggested for cleaning and disinfecting:

1. Settle the dust by spraying lightly with the disinfectant to be used. This procedure avoids undue scattering of microorganisms by dust and aerosols.

2. Take all movable equipment out of the building before starting the cleaning operation.

3. Never spread litter or droppings on the land being used for ranging turkeys or chickens. If infection is known to exist, bury or burn the litter.

4. Scrub the walls, floors, and equipment with hot lye solution made by adding 1 pound of lye to 20 gallons of hot water or with a good detergent. An old broom can be used to apply the lye solution; care should be taken to prevent the fluid from getting on the hands and face. About 1 hour after its application, the lye should be rinsed off with hot water.

Used properly, portable high pressure steam cleaning units for cleaning houses and equipment, are of great value in the cleaning and disinfection program. An advantage of using high pressure equipment is that detergents, which aid both in cleaning and decontamination, can be added to the water. Many types are available. (Example: Fig. 5.8.)

5. Spray the walls, floors, and equipment with a good disinfectant of the concentration recommended by the manufacturer. Use a compressed air sprayer for applying the disinfectant, and cover every part of the building or equipment. In modern poultry plants where ventilating ducts present a problem, steam formaldehyde techniques should be considered for decontamination of the duct system.

6. Allow time for drying before using the house and equipment again.

Certain types of hovers and brooderheating equipment are not easily washed and disinfected because of the danger of injuring them. The formaldehyde gas method recommended for disinfecting cabinet types of incubators may be used for such equipment if a gas-proof room is available.

In the early 1950's there was a wave of publicity on the merits of "built-up" or "deep litter" circulated among poultrymen. This was the result of research work stimulated by Kennard (1950) and Kennard and Chamberlin (1950) at the Ohio Agricultural Experiment Station. Moore

FIG. 5.8 — A portable steam cleaner in operation at the Poehlmann Hatchery, Petaluma, California. (S. E. Hall Co., Berkeley, Calif.)

and Chamberlin (1953) suggested "compost litter" as a more appropriate name for "deep litter" and "built-up litter." The data obtained by these investigators indicate that litter, if kept dry, need not be replaced for long periods, and that it need only be replenished from time to time with new litter. This practice is contrary to all previous ideas of proper sanitation, so in spite of the apparent successes in controlled trials, the writer believes that one should proceed with caution when using the compost-litter system.

Since ammonia fumes tend to accumulate as a result of damp litter and may cause a keratoconjunctivitis in chickens (Bullis et al., 1950; and Wright and Frank, 1957), it is important that litter be replaced if excessive ammonia fumes are detected. It is also essential that the litter be kept dry by frequent stirring, especially during the winter months. Birds should be carefully watched for signs of disease that would indicate the system is not working.

Disinfestation

Mechanical or physical means of hindering the development of parasites or destroying them are probably as important as chemical means. Cleaning the yards of all refuse, removing litter and droppings frequently, and constructing the houses so as to prevent the harboring of ticks, lice, and mites are examples of mechanical methods. All methods of fly control — cleanliness, proper care of litter and droppings, and destruction of breeding places — indirectly aid in reducing tapeworm infestation.

The methods recommended for cleaning and disinfection are also applicable in the disinfestation program. Yards are best treated by frequent cleaning and by rotation. The former dilutes the amount of infection or infestation and allows the sun better opportunity to exert its influence on the remaining parasites. Rotation of runs at regular intervals allows the sun and the other natural elements to free a given area of parasites. No satisfactory cheap disin-

festant for the soil has been found.

Plowing of the yards is not recommended unless necessary for weed control or unless a crop-rotation system is combined with the poultry-rearing program. Plowed yards soon become dusty, tend to become pitted with holes that collect water during rains, and are harder to clean than yards that are left unplowed.

DISINFECTANTS

The number of chemicals sold as disinfectants is great. Some are worthless; others are excellent disinfectants but have undesirable characteristics. Among the properties of an ideal disinfectant are (1) low cost per unit of disinfecting value, (2) ready solubility in hard water, (3) relative safety to man and animals, (4) efficient deodorization, (5) easy availability, (6) nondestructibility to utensils and fabrics, (7) stability when exposed to air, (8) absence or minimum of objectionable and lingering odor, (9) effectiveness for a large variety of infectious agents. Obviously, no one chemical will have all these properties; but the list will serve as a guide.

Many disinfectants of similar compositions are sold under different trade names. Before buying a product under an unfamiliar trade name, one should compare types and values with a well-known product. The directions for dilution given by the manufacturer should be followed in making up a disinfectant for use. These directions are usually based on the concentration of the product; and by comparing the dilution factor of two disinfectants that have other properties being equal, one can determine the relative cost of the two. For additional information and references on disinfectants and their use the reader is referred to Reddish (1957), Phillips and Warshowsky (1958), and Glick et al. (1961), as well as to textbooks on pharmacology and therapeutics.

Phenol, or Carbolic Acid

Phenol is a chemical substance obtained from coal tar. In its pure form it occurs as colorless needles having a characteristic odor familiar to everyone. It is usually sold in water solutions and is too expensive for general use. This is the chemical used as a basis for determining the phenol coefficients of disinfectants. For a complete discussion of the phenolic compounds the reader is referred to Klarmann and Wright (1957).

Cresols

Cresols are thick yellow or brown liquids, miscible with water but only slightly soluble. They form the bases for a large number of the commercial brands of disinfectants, made by combining cresol with a soap base.

A list of cresylic disinfectants which are permitted for use for official disinfection is published periodically by the United States Department of Agriculture, Agricultural Research Service, Animal Disease Eradication Division. This list (Anderson, 1961) will serve as a guide for the use of specific products.

Pine Oil

Pine oil has proved satisfactory as a disinfectant and has the advantage of being less injurious to the skin than the cresol compounds. The odor is also less objectionable. It is especially well suited for use on floors of public buildings and could be used to advantage in hatcheries, feed stores, etc. A good commercial pine oil disinfectant should contain at least 80 per cent high quality pine oil.

Hypochlorites

Chlorine is the basis of the disinfectants known as hypochlorites. Hypochlorites, according to Hadfield (1957), are available as powders containing calcium hypochlorite and sodium hypochlorite combined with hydrated trisodium phosphate and as liquids containing sodium hypochlorite.

The products containing sodium hypochlorite are essentially liquids ranging in concentrations from 1 to 15 per cent. The

15 per cent solutions are used to prepare 5 per cent solutions with water for bleaches and sanitizing agents. Germicidal potency of hypochlorites is dependent upon both the concentration of available chlorine and the pH of the solution, or upon the amount of hypochlorous acid formed which is dependent upon both these factors. The influence of pH, especially in dilute solutions, is even greater than the per cent of available chlorine. If used according to directions, hypochlorites are highly efficient. Their principal use is for disinfecting limited areas such as incubators, small brooders, and water and feed containers. *All surfaces to be disinfected with hypochlorite solutions must first be thoroughly cleaned in order to insure the greatest efficiency. Stock supplies should be kept in dark, cool places, and the containers should be tightly sealed when not in use.*

Chlorinated Lime

Chlorinated lime, known as bleaching powder, is prepared by saturating slaked lime with chlorine gas. It should contain from 30 to 35 per cent of available chlorine The U.S.D.A. Animal Disease Eradication Division recognizes chlorinated lime containing at least 30 per cent available chlorine for official disinfection when used in proportions of 1 pound to 3 gallons of water. Chlorinated lime has been largely supplanted by calcium hypochlorite products containing 70 per cent available chlorine. These products are used for chlorination of water supplies, swimming pools, sewage effluents, and for preparation of bleaching, and sanitizing solutions. Fresh solutions must be prepared daily.

All products containing chlorine must be handled with care because free chlorine is destructive to fabrics, leather, and metal.

Quicklime (Unslaked Lime, Calcium Oxide)

The action of quicklime depends on the liberation of heat and oxygen when the chemical comes in contact with water. On the poultry farm its use is limited to small yard areas that are damp and cannot be exposed to the sun, to the disinfection of drains and fecal matter, and to whitewashes. Adding chlorinated lime to quicklime at the rate of 1 pound to 40 gallons of wash increases its disinfecting value in whitewashes. As quicklime has a caustic action, birds should be kept away from it until it has become thoroughly dry.

Hydrated lime, according to Yushok and Bear (1944), when used as a preservative and deodorizing agent for poultry manure also has value as a partial disinfectant. Mixed with fresh manure at the rate of 200 pounds per ton of manure, it was found to have a bactericidal effect on *Salmonella pullorum, Salmonella typhimurium, Salmonella gallinarum,* and *Pasteurella multocida* in a 15-minute period. Similarly it prevented the sporulation of coccidial oocysts and the segmentation and embryonation of *Ascaridia galli* eggs. Another advantage of this use pointed out by them is that the treated manure is unattractive to flies and rodents. Fly maggots are not produced in the treated dropping pits, and both mice and rats avoid them.

Lye

Lye is an excellent cleansing agent, valuable in any disinfecting program. A 2 per cent solution of sodium hydroxide (soda lye) is a good disinfectant for many of the pathogenic microorganisms.

Formaldehyde

Formaldehyde is a gas, sold commercially in a 40 per cent solution (37 per cent by weight) with water under the name of formalin. For spraying it is used in a 10 per cent solution of formalin (that is, a 4 per cent solution of formaldehyde). It may also be purchased as a powder known as paraformaldehyde (paraform, triformal). When heated this powder liberates formaldehyde gas, and if used in proper portions may be substituted for formalin as a source of the gas. Manufacturer's directions on amounts to use for each type of equipment and the means of

liberating the gas must be carefully observed (see Fig. 5.10).

Though a powerful disinfectant, form-aldehyde has many disadvantages, especially its volatility, penetrating odor, caustic action, and tendency to harden the skin — properties which make it disagreeable to apply. Its chief advantages are as follows: (1) it can be used as a gas or vapor for fumigation of incubators or small rooms; (2) it is relatively nontoxic to animals and fowls; (3) it is an efficient disinfectant in the presence of organic matter; and (4) it does not injure utensils and spraying equipment with which it comes in contact.

Its use on the turkey or chicken farm is limited to disinfection of brooder equipment, incubators, water and feed containers, and occasionally — during outbreaks — fumigation of clothing and small utensils that are difficult to disinfect by other means. Fumigation of brooder houses with formaldehyde is, as a rule, impractical because of the difficulty in making them airtight.

Fumigation of incubators, incubator rooms, and holding rooms is a practical procedure. Most incubator manufacturers have recommendations for their type of machine; and their directions should be followed.

The National Poultry and Turkey Improvement Plans (1963) describe in detail the official recommendations for hatchery sanitation including incubator fumigation. When fumigating a room or an incubator, one must have the space airtight and the room temperature and humidity as high as possible. For most efficient disinfection of incubators, Bushnell and Payne (1931) recommend a wet-bulb thermometer reading of 85° to 95° F. Disinfection is uncertain in rooms having a temperature of less than 70° and a relative humidity of less than 70 per cent.

Formaldehyde gas may be liberated from formalin-soaked cheesecloth by the technique described by Graham and Michael (1933). When this method is used the incubator must be thoroughly dry-cleaned. Approximately 20 cc. of formalin is then used for each 100 cubic feet of incubator space. A series of saturated cloths with total area enough to carry the formalin without dripping is suspended under or near the circulating fans, and left until the formalin has completely evaporated.

Formaldehyde gas is most often generated by mixing formalin (40 per cent formaldehyde) and potassium permanganate. For routine purposes 35 cc. (1.2 ounces) of commercial formalin and 17.5 grams (0.6 ounce) of potassium permanganate for each 100 cubic feet of incubator space are mixed together in an earthenware or enamelware vessel having a volume of four to five times the amount of material used. The vessel should be placed above the floor in the middle compartment of the incubator (Fig. 5.9). The doors should be kept closed for at least 10 minutes to allow the gas to penetrate to all parts of the machine. Equipment for generating and introducing the gas through the intake parts of certain types of machines is obtainable from the manufacturers.

Insko et al. (1941) and Insko (1949) recommend using from two to three times the normal amount of potassium permanganate and formalin between hatches when omphalitis is being transmitted in an incubator. Figure 5.10 illustrates one method of heating paraformaldehyde powder to liberate formaldehyde gas. This electric pan should be equipped with a thermostat and a timer which can be controlled from outside the incubator or fumigation chamber.

Formaldehyde can be used successfully when eggs are in the incubator. Insko et al. (1941) and Insko (1949) warn against fumigation during the first three days of incubation because the embryos are then most susceptible to formaldehyde. Fumigation with formaldehyde destroys or attenuates the pathogenic organisms in the incubator, but not within the egg nor within the body of the hatching chick or poult. Its principal use, therefore, is in

FIG. 5.9 — A method of fumigating an incubator with potassium permanganate and formalin. (Graham and Michael, Univ. of Ill., 1933.)

FIG. 5.10 — An electrically heated pan for use in liberating formaldehyde gas from paraformaldehyde. (Vineland Poultry Laboratories photo.)

disinfecting incubators between hatches and, in some instances, during the early stages of a hatch. Before fumigation of incubators during the hatching period, advice should be sought from one familiar with the procedure to determine the possible need and methods. *In general, fumigation of hatching chicks or poults is not recommended.* Precincubation fumigation of hatching eggs as an aid in prevention of salmonellosis is described by Stover (1960). The method used by him is essentially that used for incubator fumigation.

The use of formaldehyde, as well as other gaseous sterilization techniques, is discussed in detail by Phillips (1957) and by Glick *et al.* (1961). A method, referred to by them, which is used for decontamination of large enclosed areas, could be adapted for use by the poultry industry, especially for use in ventilating systems of large broiler-producing plants. It consists of liberation of formaldehyde gas by steam. In this system, commercial grade formaldehyde solution (37 per cent) with 12 per cent methanol (5 parts 37 per cent formaldehyde, and 3 parts methyl alcohol adjusted to pH 5.0) is liberated into the space by a steam ejector. One ml. of formaldehyde solution is disseminated for each cubic foot of air flow for 30 minutes; i.e., if the air flow is 600 c.f.m., then (600 x 1 x 30) 18,000 ml. of formaldehyde solution will be disseminated in 30 minutes. The temperature of the space to be decontaminated must be maintained at above 70° F. and the relative humidity above 70 per cent. Proper temperature and humidity may be assured by allowing the steam ejector to operate for a few minutes before adding the formaldehyde solution. The purpose of adding methanol to the formaldehyde is to reduce deposits of polymers on interior surfaces of the treated spaces.

For smaller space areas such as cabinets, small rooms, and incubators, a portable vaporizer such as the Hydro-mist Vaporizer, Model H, shown in Fig. 5.11 may be used to disperse the formaldehyde gas.[1] This and other types commonly used for decontamination of air filtration systems are described by Decker *et al.* (1962).

Ethylene Oxide

Ethylene oxide is a colorless gas at ordinary temperatures, liquefying readily at 10.8° C. and freezing at –111.3° C. The liquid is miscible with water and all organic solvents in all proportions. It is highly flammable and for this reason is dangerous to use by itself. It is now extensively used in the form of a low-pressure mixture with nonflammable chlorofluorohydrocarbons (Freons) in a disposable 16-oz. can (Haenni *et al.*, 1959). Chambers for utilization of such mixtures are described by Schley *et al.* (1960) and Glick *et al.* (1961).

It probably has limited use on poultry farms, hatcheries, or processing plants, because of its flammability and need for dispensing under slight pressure. It does, however, have many advantages over formaldehyde gas and has been shown to be effective against many poultry pathogens including viruses. Mathews and Hofstad (1953) showed that ethylene oxide was effective against 15 animal viruses including the viruses of infectious laryngotracheitis, fowl pox, infectious bronchitis, and Newcastle disease. Lorenz *et al.* (1950) used it successfully to prevent penetration of *Pseudomonas* sp. through the shells of eggs.

The penetrating properties are excellent, and for this reason it might prove of value for sterilizing litter, feed, and certain equipment. Unlike formaldehyde, ethylene oxide gas is more reactive at lower relative humidities. Phillips (1957) states that the advantages of ethylene oxide sterilization are not in the speed, simplicity, or inexpensiveness of the treatment, but rather in the fact that many types of materials can

---

FIG. 5.11 — A steam-pressure vaporizer as illustrated can be used for dispersing formaldehyde gas for decontaminating small space areas. (U. S. Army photo.)
be sterilized with the least damage to the material. For a complete review on this method of disinfection the reader is referred to Phillips' report.

Beta-Propiolactone (BPL)

Beta-propiolactone (BPL) is a newcomer in the field of vapor disinfectants (Hoffman and Warshowsky, 1958; and Glick et al., 1961). BPL more nearly resembles formaldehyde than it does ethylene oxide in its germicidal properties. According to Hoffman and Warshowsky, it possesses a number of advantages over formaldehyde as a gaseous sterilant, especially with respect to increased antimicrobial activity and lessened persistency. It does not polymerize readily on surfaces so leaves little or no residue. In a liquid state it is more toxic than formaldehyde and care must be taken to avoid contact with the skin.

Vaporizers suitable for dissemination of formaldehyde are suitable for BPL (Fig. 5.11). One gallon of lactone is vaporized for each 12,000 cubic feet of space (Spiner and Hoffman, 1960).

It acts more rapidly, but can be used under the same conditions as formaldehyde. Rooms do not need to be hermetically sealed but doors and windows should be closed. After a hold period of 2–3 hours, doors and windows may be opened and forced ventilation applied. It is necessary to enter a room or building only with protective clothing and respiratory protection until proper airing of 2–3 hours has been allowed.

Copper Sulfate (Bluestone)

Although copper sulfate and other salts of copper have a marked toxic effect upon some of the lower forms of life, they are not considered good general disinfectants. Copper sulfate is effective against algae and certain fungi and may prove of some value in outbreaks of fungus diseases. Copper sulfate of a greater concentration than 1 part in 500 of water may be toxic when given as the only source of drinking water. Turkeys do not like copper sulfate solutions of any concentration and will seek other water supplies if they are available.

A 1:2,000 concentration of copper sulfate in drinking water will be consumed readily, if no other drinking water is available. A 0.5 per cent solution may be of value for disinfecting feed hoppers, water fountains, and areas around these in fungous-disease outbreaks.

Mercuric Chloride (Bichloride of Mercury, Corrosive Sublimate)

Although a powerful disinfectant, mercuric chloride is limited in usefulness by its cost, toxicity, and marked corrosive action on metals. It is commonly used in 1:1,000 dilution with water. Because its value is markedly lowered by the presence of organic matter and because it has certain other undesirable properties, it cannot be recommended for disinfection of litter or houses.

Quaternary Ammonium Compounds

Within the past few years much publicity has been given to the disinfecting value of quaternary ammonium salts. There are a number of these products now on the market, and they are generally considered to be good disinfectants if used according to directions. They are water clear, odorless, nonirritating to the skin, good deodorants, and have a marked detergent action. These compounds are recommended especially for disinfection of eggs and for general use around the hatchery. It is important to remember that quaternary ammonium compounds cannot be used in soapy solutions. It is also important that all surfaces to be disinfected be thoroughly rinsed with water to remove any residue of soap or anionic detergent before using a "quat" for sterilizing purposes. An excellent reference on quaternary ammonium compounds is Lawrence (1957).

Sunlight and Ultraviolet Radiation

The sun's direct rays are the best disinfectant known. Since, however, the material to be treated must be in thin layers and exposed to the direct rays, this method of disinfection is limited to yards and to utensils that can be thoroughly cleaned before being exposed. The construction of most poultry houses prevents efficient disinfection by the sun. A cement platform fully exposed to the sun makes a convenient place for treating movable equipment. If properly constructed with a drain, such a platform can be utilized as a washing and disinfection rack.

There are many types of germicidal (ultraviolet) lamps now being advertised for use on the poultry farm and in the hatchery, but there is not enough scientific evidence available to warrant a recommendation for their general use. For a complete review on the use of UV radiation in microbiological laboratories the reader is referred to Phillips and Hanel (1960).

Hot Water

Hot water adds to the efficiency of any disinfectant and, if applied in the form of boiling water or live steam, is effective without the addition of any chemical. Detergents added to systems for generating and disseminating hot water and steam will increase cleaning and decontaminating efficiency. Live steam must be applied directly to the part to be disinfected (see Fig. 5.8).

Dry Heat

Dry heat in the form of a flame is effective provided the flame comes into contact with the bacteria to be killed. According to experiments by Stafseth and Camargo (1935), the fire guns commonly used on poultry farms are not highly efficient as a means of disinfection. *All methods involving direct flame are dangerous fire hazards.*

Central heating systems, construction of poultry houses to utilize solar heat, and these combined with air conditioning and proper humidity control are trends of modern poultry management research. Agricultural engineers are currently doing much research on these problems in attempts to control moisture in poultry houses. Application of principles being de-

veloped will have a marked effect on future sanitation recommendations. The reader is urged to keep abreast with such developments in order to be in a position to make use of them in disease prevention programs.

DISINFESTANTS

Disinfestants, sometimes called parasiticides, destroy animal parasites such as lice, mites, ticks, and fleas. Their use is recommended only as an adjunct to a properly conducted sanitary control program. Many disinfestants are also destructive to lice, mites, and other similar parasites, provided they come in contact with the parasite. Many, however, are useless as disinfestants.

The possible hazards to man and other animals from use of many of the modern pesticides must always be remembered when considering their use. A recent review reference on this subject is Rogoff (1961).

Crude Oil, Distillates, and Similar Cheap Oils

Petroleum oils are excellent and cheap agents for the destruction of lice, mites, and ticks but have been largely replaced by the efficient and easier to apply, more recently developed insecticides (DDT, lindane, malathion, etc.).

Bullis and Van Roekel (1944) have reported that exposure of chicks to the fumes of coal-tar creosote oil, anthracene oil, and certain mite paints too soon after use in a brooder house may cause anasarca (ascites, watery belly).

Nicotine Sulfate

A 40 per cent solution of nicotine sulfate, such as is sold under the trade name of Black Leaf 40, once in general use for controlling lice, has been largely replaced by newer pesticides. Its action depends on a volatile substance that penetrates the feathers of the birds when it is painted on the perches just before they go to roost. The method is not well adapted to control of lice on turkeys under rearing conditions

where the perches are usually placed out of doors.

Sodium Fluoride

This, either as a dust or as a dip, is effective for ridding birds of lice. The dusting method is probably the most desirable. It consists of rubbing a pinch or two of the powder into the parts most often infested with lice (on the tail, under the wings, on the neck and head, and on the breast). As in the case of nicotine sulfate, it has been largely replaced by newer pesticides.

DDT (Dichloro-diphenyl-trichloroethane)

Certain precautions must be given in the use of this much-publicized insecticide. In areas where DDT has been used extensively in fly control, resistant strains of flies have developed to such an extent as to render DDT almost valueless for their control. Because of widespread development of DDT-resistant species of all insects, it has been largely replaced by more recently developed insecticides discussed below. The hazards in its use have also been proved to be greater than originally thought. When DDT is used on farms, wettable powders are probably the most usable type. DDT is effective against mosquitos, the fowl tick, and the black fly (Simulium), provided susceptible strains exist, but is no more effective against lice than sodium fluoride.

Malathion (O, O-dimethyl dithiophosphate of diethyl mercaptosuccinate)

This drug is effective against lice, mites, and flies, and may be used as a spray in a 0.5 per cent emulsion or as dust when applicable. The U.S. Food and Drug Administration has accepted it for direct application as dust and has set a residue tolerance of 4 parts per million as the amount which can be safely found in meat. They require a zero tolerance in eggs. Furman and Coates (1957) found it effective against the Northern fowl mite

FIG. 5.12 — Use of Burdizza forceps in killing a turkey. When brought into a closed position carefully the jaws separate the vertebrae and sever the spinal cord and jugular vein without breaking the skin. (Hinshaw, Univ. of Calif.)

shedding of blood and thus prevent the spread of infections that are present in the blood stream. A convenient tool for the purpose is a Burdizza forceps like that used for castrating calves (Fig. 5.12). Another means of killing birds for necropsy is by electrocution.

4. Burn or bury dead birds. If buried, they should be placed deep enough to insure their not being dug up by dogs or other animals. See section on Disinfection for recommendations on disposal of droppings, and use of litter for disinfection procedures.

A disposal pit such as is illustrated in Fig. 5.13 is superior to incineration as conducted on most poultry farms and by hatcheries. Such pits are easily and cheaply constructed and are efficient. The roof of such pits and especially the "manhole" covering must be airtight to prevent escape of odors and avoid the attraction of flies. Periodic spraying of the roof of the pit with an insecticide is suggested. Open disposal pits are not recommended.

An electrically heated septic tank for disposal of dead birds and waste products on large poultry farms and processing plants has been developed by U.S.D.A., A.R.S., in cooperation with the Maine and Connecticut Agricultural Experiment Stations (Agriculture Research 5(9):14, Mar., 1957). The method consists of digesting

the carcasses and/or waste products in a heated septic tank. A 500 gallon tank will meet the needs of a 10,000 to 20,000 broiler farm. Heat is applied at 100° F. and requires 2 to 3 kilowatt hours of electricity per day to maintain this daily temperature
FIG. 5.13 — Poultry disposal pit. Such a pit can be made any size that is convenient, and is valuable for disposal of hatchery wastes as well as carcasses. (Hinshaw, Univ. of Calif.)

for the two weeks needed for destruction of all but the bones of carcasses. The system depends on mesophilic bacteria which multiply best at 90° to 100° F. to accelerate decomposition. Neutralizing the mass at intervals with lime and adding hot water further accelerates the action and speed of decomposition.

5. Thoroughly clean and disinfect all houses and equipment. If the affected birds are in yards, these should be cleaned of all refuse to allow the sun to aid in disinfecting all parts.

6. Keep fresh water before the birds at all times. The water containers should be thoroughly washed and disinfected at least once daily. If medicated water is necessary, it is essential that drugs which are specific for the disease are used and that they are not distasteful to the birds. Birds do have the ability to taste and will seek other sources or go without water if it is distasteful. It is also essential to have enough waterers available so that the birds do not have to walk more than 8 to 10 feet to get a drink. If automatic medicators are installed in watering systems that depend on gravity for delivery to the birds, it is necessary that the elevation is great enough to insure delivery of proper mixtures to all the fountains. Stagnant pools or irrigation ditches should be fenced off so the birds cannot use water from them.

7. Clean and disinfect thoroughly all feed hoppers daily.

8. Thoroughly inspect the food to determine the possible presence of decayed fish or meat scraps, spoiled milk, moldy grain, poisonous weeds, or other sources of possible trouble.

9. Avoid sudden changes of feed. If the feed is the cause of the trouble, a new diet is warranted; but any changes should be made by gradually increasing the new formula.

10. The convalescent stage of any disease is the most important one. Poults or chicks die from lack of feed and water in a very short time. Getting them to eat after they have been ill, even for a short time, is often a very difficult task. It must be accomplished, however, if the mortality is to be reduced to a minimum. Feeding small quantities of mash at frequent intervals often aids in restoring feeding habits.

Here again is emphasized the importance of having enough waterers and feeders so that a bird does not have to walk over 8 to 10 feet to eat or drink (Fig. 5.14). Waterers need to be in close proximity to feeders. Often convalescing birds can be encouraged to eat and/or drink by frequent visits to the pen or house by an attendant. He should not only look into the house, but should wander among the birds, adjust waterers, stir the feed in hoppers, or add small amounts of feed. All these tasks cause birds to become active and eat at least small quantities.
FIG. 5.14 — It is essential to have plenty of feeders and waterers in close proximity to each other. (Everybody's Poultry Magazine.)

Proteins, Carbohydrates, Fats, Fiber, Minerals, and Water in Poultry Feeding

In order to maintain poultry in good physical condition and to obtain normal growth, egg production, and hatchability, rations must be fed that are adequate in all nutritive essentials. Whenever a serious deficiency of any one of these essential substances occurs, symptoms of deficiency develop which in some instances are characteristic. These are frequently preceded and accompanied by nonspecific symptoms such as retarded, uneven growth; rough feather development; decreased egg production; and lowered hatchability. When the deficiency is only a partial one, these may be the only symptoms which are observed. This makes it difficult to recognize the partial deficiency since the nonspecific symptoms may be brought about by a number of causes, including disease. A good background in the nutrition of poultry, therefore, is necessary for all persons interested in poultry feeding, management, sanitation, and disease.

The nutritive substances of importance in the nutrition of poultry are (1) proteins and amino acids, (2) carbohydrates, (3) fats, (4) minerals, (5) vitamins, known and unknown, and (6) water. The discussions in this chapter include all of the groups of nutritive substances except the vitamins, which are discussed in Chapter 7.

THE PROTEINS AND AMINO ACIDS

The proteins are needed by poultry for the synthesis of new body tissue required in growth, to replace body proteins broken down in maintenance, and to furnish the proteins required for egg formation.

Composition of proteins. Proteins are complex substances composed of amino acids linked together in chemical combination. The amino acids consist of carbon, hydrogen, oxygen, nitrogen, and in two instances, sulfur. Approximately twenty different amino acids have been isolated from proteins. The number of amino acids in each protein as well as the percentage of each is characteristic. Because of this a great many proteins are possible, and

many exist in nature. Every feedstuff contains a number of different proteins.

Digestion of proteins. Proteins are not absorbed from the intestinal tract as such but are broken down during digestion into their constituent amino acids by proteolytic enzymes secreted into the gastric, pancreatic, and intestinal fluids. Some dipeptides, however, are absorbed and split into their constituent amino acids in the intestinal mucosal cells. After absorption the amino acids are then rebuilt into characteristic body and egg proteins.

Protein requirements of poultry. The value of proteins for growth and egg production depends upon their amino acid compositions. Originally it was impossible to use this knowledge because reasonably complete information concerning the amino acid content of the proteins of feedstuffs and the quantitative amino acid requirements of poultry was lacking. Therefore, in investigating the requirements of poultry for protein, extensive studies were made of the supplementary relationships existing between feed proteins. These studies showed that for best results combinations of the mixed proteins of a number of different ingredients were necessary and that, with the exception of soybean protein, the inclusion of some protein of animal origin in the over-all combination of proteins was required. Such a combination of proteins was said to be of good quality, since in all probability the combined proteins of the feed mixtures contained all of the essential amino acids in the right proportions and amounts for maximum growth or egg production.

Experiments on the protein requirement for growth of chicks reviewed by Heuser (1941) and Hill (1944) showed that, when the ration contains a protein mixture of good quality, approximately 20 per cent of protein is required in order to promote rapid growth during the first few weeks of life. The findings presented in these reviews were confirmed in studies reported by Singsen (1947) and Hill (1949). The results showed that as good growth was obtained in crossbred chicks from diets containing either 20 or 21 per cent protein as was obtained from diets containing larger amounts.

At about this time, Heuser et al. (1945) showed that the substitution of feedstuffs of high digestibility for those of low digestibility increased chick growth and egg production, and Scott et al. (1947) reported that combinations of corn and wheat resulted in better growth of broilers, whereas replacing the corn progressively with increasing quantities of pulverized oats depressed growth and the efficiency of feed utilization. The results of these experiments led to the realization that more attention must be given to the energy content of poultry rations than had been done previously.

As a consequence, the quantitative relationship between the available energy in poultry rations and the protein content has been studied extensively by Combs and Romoser (1955), Sunde (1956), Donaldson et al. (1956), Ferguson et al. (1957), Miller et al. (1957), Atkinson et al. (1957), Day and Hill (1957), and Hill and Renner (1957). The results of their experiments showed that the protein requirements of poultry increase as the energy content of the diet increases and that the requirements, therefore, can no longer be expressed as percentages of the diet, but rather should be expressed as energy-protein ratios. The results also showed that the requirement of the chick for 20 per cent of protein during early life applies only to diets of medium energy content. The estimated protein requirements of poultry presented as energy-protein ratios based on the work of these investigators, general knowledge of protein requirements, and relationship of requirements to growth rate, mature size, and rate of egg production are given in Table 6.1.

Other factors which influence protein requirements and thus energy-protein ratios are environmental temperature, the extent to which exercise is restricted, and the finish desired in market poultry. In a

warm environment, less heat is required to maintain body temperature than in a cold environment. This makes possible a somewhat narrower energy-protein ratio. When exercise is severely restricted, as when hens are confined to individual cages, the energy requirement is reduced, and a somewhat narrower energy-protein ratio is desirable in order to prevent the hens from becoming too fat. If the energy-protein ratio is too wide, too much fat may be deposited in the tissues in poultry fed for market, the carcass quality is reduced, and feed conversion is decreased. Thus the estimated energy-protein ratios in Table 6.1 not only may change with the future development of more precise information on the needs of poultry for protein, but also may change with the factors known to affect the protein requirement.

The energy-protein ratios given in Table 6.1 are presented here both as metabolizable energy-protein ratios and as productive energy-protein ratios. Metabolizable

energy (ME) is the energy remaining after subtracting from the gross food energy, as determined by combustion in a bomb calorimeter, the energy losses similarly determined from the undigested residues of food and substances secreted into the gut, and the incompletely oxidized products of the urine. Productive energy (PE) is that portion of the metabolizable energy which is available for the formation of protein and fat in the growing chicken and in eggs. It represents approximately 70 per cent of the metabolizable energy. The remainder is lost largely through the production of heat arising from the chemical reactions occurring in metabolism as a consequence of normal body activities and the maintenance of body temperature.

Fraps (1946) presented the results of an exhaustive study of the productive energy content of poultry feedstuffs, and Hill et al. (1960), Hill and Renner (1960), Potter and Matterson (1960), Sibbold and Slinger (1962), and Stutz and Matterson

(1962) reported values for the metaboliz-able energy content of many of these materials. Hill and Anderson (1958) and Potter et al. (1960) showed that the metabolizable energy values of feedstuffs can be determined more precisely, and thus are more accurate than the productive energy values determined by Fraps (1946).

The variation in the protein requirement of the chick with age is due to the fact that in growth much of the protein in the diet is required for the formation of new body tissue and little is required for maintenance. Because of faster rate of growth the formation of new body tissue by chicks is greatest during the first few weeks after hatching. Thereafter it gradually declines and becomes zero as the chick attains maturity. More protein is therefore required during early chick life than during the period preceding cessation of growth.

The diet of the chick, therefore, does not need to contain 20 per cent protein longer than the first 4 weeks after hatching. Thereafter, the protein content of the diet, according to Heuser (1941), can be reduced by 2 per cent at 4-week intervals but should not be decreased below 15 per cent for pullets during the final period of growth. At this time, when the growth rate is slow, egg production usually begins, which increases the need for protein. The protein requirement of nonlaying chickens, however, probably declines to 12 to 14 per cent before growth finally ceases.

Since the heavier breeds of chickens grow somewhat faster than White Leghorns, their protein requirements should be somewhat greater, particularly during the earlier stages of growth. The results of an investigation carried out in Australia (Anonymous, 1935) showed that chicks of Light Sussex and Australorp breeds made better gains when a high protein ration was fed to 9 weeks of age, while White Leghorns grew equally well when the protein level was reduced at 6 weeks. Mitchell et al. (1926a, 1931), as a result of studies of growth changes in chickens, concluded

that the protein requirement of White Plymouth Rock chicks is greater than that of White Leghorn chicks.

The rations of laying and breeding hens at medium energy levels should contain approximately 15 per cent protein. Heuser (1936) found that a ration containing 12 per cent protein failed to maintain either satisfactory egg production, egg size or body weight, while a ration containing 14 per cent gave satisfactory egg production but did not maintain body weight at all times and was not conducive to best egg size. Satisfactory maintenance of weight and satisfactory egg size, however, were obtained when the ration contained 15 to 16 per cent protein. Results similar to those of Heuser were obtained by Heiman et al. (1936).

The protein requirement varies somewhat, however, with different strains of hens. Some hens have been reported to give satisfactory egg production on rations containing as little as 15 per cent protein. The protein requirement of hens obviously also varies with the rate of egg production. When hens are not laying, the protein requirement is probably in the neighborhood of 12 per cent. The protein requirement of the molting hen does not appear to have been studied. However, it is presumably somewhat greater than that of the nonlaying hen, since the production of a new coat of feathers increases the need for protein. Reviews of the experimental work on the protein requirements of hens have been made by Heuser (1941) and Hill (1941).

The results of research work on the protein requirement of turkey poults, conducted by Funk and Margolf (1932), Headley and Knight (1938), and Mussell et al. (1941), and of experiments conducted at the Cornell University Agricultural Experiment Station reported by Smith and Weaver (1936) indicated that for rapid growth a ration containing at least 24 per cent protein of good quality is necessary. Shortly afterwards, however, Fritz et al. (1947) and Scott et al. (1948).

using rations that were more adequate nutritionally, found that the protein requirement for turkey poults for maximum growth is approximately 28 per cent of the ration. The rations fed the turkey poults in these investigations were of medium energy content.

The protein requirement of poults declines with decreased rate of growth in a manner similar to that of chicks. At medium energy levels the protein content of the diet may be lowered to 24 per cent at 4 weeks of age, 20 per cent at 8 weeks of age, 18 per cent at 12 weeks of age, and 16 per cent at 16 weeks of age until maturity is reached.

In an investigation of the protein requirement of turkey breeders, Jensen and McGinnis (1961) concluded from the results of three experiments that a ration containing 15 per cent protein would be adequate under most conditions. In the third experiment, however, results believed to be satisfactory were obtained with 10 per cent protein, although slightly better egg weight and hatchability of fertile eggs occurred at 12 per cent protein and maximum egg production was attained at 14 per cent protein.

The protein requirement of ducks has not been completely worked out. Horton (1932) observed that ducklings grew at a much faster rate when fed a ration containing 19 per cent protein than when fed one containing 12 per cent. Hamlyn et al. (1934) obtained somewhat better growth in ducklings at 4 weeks of age when rations were fed containing approximately 20 per cent rather than 17.5 per cent protein.

More recently Scott and Heuser (1951) reported better early growth in ducklings supplied rations containing 17 to 19 per cent instead of 15 per cent protein. The difference in favor of the higher protein rations, however, disappeared by the time the ducklings reached 8 weeks of age. The results of additional experimental work conducted by Scott et al. (1959) indicate that the ducklings fed the lower protein ration to market age were of higher fat and lower protein content than the ducklings receiving the higher protein rations.

The protein requirement of starting and growing ducklings, given in the National Academy of Sciences-National Research Council (NAS-NRC) "Nutrient Requirements for Poultry" (1960b), is 17 per cent.

per cent of the phosphorus of plant sources may be considered a part of the inorganic phosphorus.

Ducklings given this quantity of protein may not grow as fast during the first week or two as those receiving 18 to 20 per cent. However, they later will recover from the slight growth retardation and weigh at market age as much as those provided more protein at the start. For economic reasons the general practice at present is to feed ducklings rations containing 18 per cent protein for the first two weeks and 15 per cent from this time to market age. These rations are usually of medium to high energy content.

The quantities of protein required in rations of medium energy content for chickens and turkeys are given in Tables 6.2 and 6.3. The values were taken from the most part from the NAS-NRC "Nutrient Requirements for Poultry" (1960b).

Amino acid requirements of poultry. Some of the amino acids found in proteins are essential for maintenance and growth of the chick and therefore must be present in the ration in adequate quantities. These are listed in Table 6.4. Alanine, aspartic acid, hydroxyproline, norleucine, proline, and serine are synthesized in the body of the chick and may be dispensed with. Cystine and tyrosine are not required ex-

cept for their sparing effect on methionine and phenylalanine respectively. Glycine and perhaps glutamic acid are synthesized to a limited extent but not in sufficient amounts to promote rapid growth.

Although the dispensable amino acids are not nutritionally essential in the ordinary sense, they are needed by the chick in building body protein. A ration which supplies all the essential amino acids in just the right proportions to meet the specific needs for them is not adequate because it does not contain enough amino acid nitrogen to permit the synthesis of all of the protein required for maintenance, rapid growth and egg production.

Almquist (1947, 1952) discussed the available evidence on the quantitative amino acid requirements of chickens and turkeys. Edwards et al. (1956) found that the quantitative requirement of the chick for lysine was 1.1 per cent of a diet containing 20.0 per cent protein. Using pure amino acid mixtures, Klain et al. (1960) and Greene et al. (1960) restudied the quantitative amino acid requirements of the chick. Similar studies with laying hens, using pure amino acids, have been conducted by Johnson and Fisher (1958). The amino acid re-

[a] The data on the amino acid requirements of chickens and turkey poults were obtained from the NAS-NRC "Nutrient Requirements for Poultry," 1960b.

quirements of laying hens are qualitatively similar to those of chicks, but the quantities of the amino acids needed to meet their requirements are somewhat less than those of rapidly growing chicks, because of the lower total protein requirement.

Information on the amino acid requirements of turkey poults is incomplete. The results of Snetsinger et al (1962), using pure amino acids, and those reviewed by Almquist (1952) indicate, however, that the amino acid requirements of poults are at least qualitatively similar to those of the chick, although the evidence indicates the quantitative requirements may be somewhat greater. This is to be expected in view of the more rapid growth rate and higher protein requirement of poults.

The NAS-NRC (1960b) amino acid requirements of chickens and turkeys are based largely on the reports just discussed. These values are presented in Table 6.4.

The essential amino acid composition of the more common poultry feedstuffs is

presented in Table 6.5. The data given in the table show that the amino acid composition of the mixed proteins of feedstuffs is not uniform. These differences in amino acid composition are of great practical significance since they make it necessary to use several different feedstuffs in building poultry rations in order to meet the amino acid requirements without undue wastage of protein. Attempts to meet the requirement for an essential amino acid by increasing the amount of protein in the ration do not appear to be satisfactory. Grau and Kamei (1950) have shown that as the protein level in the chick ration is increased, the lysine and methionine plus cystine requirements are also increased, but at a slower rate. This indicates that protein in considerable excess is needed in order to meet a slight deficiency of these amino acids.

The data on amino acid content of feedstuffs given in Table 6.5 make it no longer necessary to depend entirely upon the knowledge of the supplementary relationships of protein to obtain protein of good quality in poultry rations. The amino acid content of the ration can now be calculated from the data and compared with the requirement. By doing this, greater assurance is obtained that the mixed proteins in the ration are combined in such a way as to give a protein combination of optimum quality.

Other functions of amino acids. Amino acids fulfil many other functions aside from their main one as building stones for the protein required in growth, maintenance, and egg production. Creatine, which is physiologically essential for the functioning of muscular tissue, is synthesized in the body from arginine, methionine, and glycine. The amino acid, tyrosine, is used in the formation of the hormone, thyroxine, and certain pigments in the feathers of colored fowl. Lysine has been shown to be needed in some indirect way for feather pigment formation in turkeys. Fritz et al. (1946) observed feather achroma in Bronze turkeys fed a corn gluten meal diet which was corrected by the addition of

lysine. The picture in Figure 6.1 shows the abnormal white wing feathers of Bronze poults caused by lysine deficiency.

Methionine is a source of methyl groups for methylation processes in the body and either exerts a sparing effect on choline or takes part in the synthesis of choline when other necessary precursors are present in the ration. The amino acid, tryptophan, is converted into nicotinic acid in the developing chicken embryo, according to evidence obtained by Schweigert et al. (1948). Briggs et al. (1946) reported that either tryptophan or nicotinic acid overcomes the growth depressing effects obtained on feeding chicks a low-tryptophan, low-nicotinic acid diet

Effect of heat upon protein quality. Experimental results have shown that moderate heat treatment greatly improves the quality of soybean proteins for poultry by destroying an inhibitor which interferes with digestion. The poor quality of raw soybean protein was found to be due not to the presence of a heat-labile trypsin inhibitor in the bean, but rather to the presence of some other factor which inhibits the rate of growth (Evans et al., 1947; Borchers et al., 1948; Borchers and Ackerson, 1950). The results of Hayward and Hafner (1941), Almquist et al. (1942), and Melnick et al. (1946) indicate that the growth inhibitor slows the rate of digestion of the amino acid methionine relative to the other amino acids. This could account for the retarded growth obtained by feeding raw soybeans, as the absorbed amino acids would not be in proper proportion for efficient protein synthesis.

Prolonged heat treatment at high temperatures, on the other hand, decreases the quality of proteins, including those of soybeans. Experiments indicate that the amino acid lysine is affected most by drastic heat treatment but that arginine, tryptophan, and histidine are also affected (Riesen et al., 1947; Patton et al., 1948a, 1948b). The loss of availability of these amino acids is largely due to combination with reducing sugars, but Evans and Butts (1948) showed that, while a portion of
FIG. 6.1 — Lack of normal feather pigmentation in a Bronze poult caused by a deficiency of lysine.

these amino acids is completely inactivated, the rate of digestion of the remainder is slowed up so as to make them incompletely available during a limited digestion period.

Sources of protein. The feedstuffs which are commonly used as protein supplements in poultry rations at the present time are soybean meal, meat scrap, and fish meal. Peanut meal and corn gluten meal are used to a limited extent but are not important sources of protein for feeding poultry. With the development of a method for detoxifying cottonseed meal (Boatner and Hall, 1946; Groschke et al., 1947), it is possible to make this product satisfactory for use as a source of protein. However, none of the vegetable protein supplements except soybean meal contain protein of approximately the same composition of essential amino acids as the proteins of meat scrap and fish meal. The chief amino acid deficiency is lysine. Hence the vegetable proteins are not particularly adapted in general for poultry feeding. Evidence indicates (Heuser et al., 1946), however, that satisfactory growth can be obtained by combining corn gluten meal, cottonseed meal, and peanut meal in limited quantities with soybean meal and with meat scrap and fish meal.

Dried skim milk and dried buttermilk are also excellent sources of protein of superior quality. Their protein content, however, is lower than that of the protein supplements just discussed. They are used in poultry rations more for their content of essential vitamins than for proteins because of relatively high cost.

Influence of protein level upon start of egg production. The protein level of the ration fed to chicks and growing pullets appears to have little effect on the age at which the pullets begin to lay or upon subsequent egg production except when it is low enough to retard growth greatly. Carver et al. (1932), however, reported that a protein level of 12 per cent retarded the age of sexual maturity of White Leghorn pullets from 25 to 40 days, but subsequent results of other workers on the

riboflavin requirements showed that the low-protein ration was greatly deficient in this vitamin. Later Carver et al. (1939) reported that pullets fed rations containing 19 per cent protein reached sexual maturity a few days earlier than those fed rations containing 13 per cent. Several other groups of investigators (Winter et al., 1932; Morris et al., 1932; Heuser and Norris, 1933; Byerly et al., 1933; Tepper et al., 1939) have obtained results indicating that the rate of attaining sexual maturity is not influenced to any marked degree by the protein content of the ration.

Carver et al. (1939) fed protein levels varying from 13 to 19 per cent during the first 22 weeks after hatching and 15.3 per cent thereafter, and found during the first 224 days of production that neither the egg weight nor the rate of egg production was influenced by the quantity of protein fed during the growing period. Bronkhorst (1938) also found that egg yield was not affected by the amount of protein fed growing pullets during the prelaying period.

Protein level and feathering. Because feathers are composed chiefly of protein, it is obvious that poor feathering will result from lack of adequate protein in the ration. Tomhave (1939) showed that when the protein level in the ration was less than 18 per cent during the first 8 weeks, bare breasts occurred in White Leghorn pullets. Several other investigators (Gericke and Platt, 1932; McConachie et al., 1935; Ackerson et al., 1939) reported that feather development improved as the protein level in the ration was increased. A possible relationship between the protein content of the ration and feather pulling, tail picking, and cannibalism was reported by Margolf (1929). In his experiment, these vices developed in chicks fed low protein rations as early as the second and third weeks.

Excess protein. The question as to whether the feeding of excess protein to chickens is harmful remains unsettled. Milne (1932) and McConachie et al. (1935) reported detrimental effects upon growth rate of chicks when the protein

level of the ration was raised to 30 per cent or more. The latter observed high mortality at a 35 per cent level. Lloyd et al. (1949) found that a protein level of 36 per cent in one experiment with turkeys was apparently toxic but that approximately 35 per cent protein gave good results when the ration was a high-energy, low-fiber type. Almquist and Asmundson (1944) obtained improved growth of chicks fed a 30 per cent protein ration.

Uremic poisoning. Patterson (1928) suggested that nutritional gout or uremic poisoning in chickens, except that caused by vitamin A deficiency, may be due to the feeding of excess nitrogenous concentrates. This condition, which is characterized by internal deposits of sodium urate, particularly in the kidneys and ureters, has been observed also by other workers (Mayall, 1929; Hartwigk, 1931; Bird et al., 1946). Each of these workers appears to have a different explanation for the cause of this condition.

In support of Patterson's (1928) suggestion, Schlotthauer and Bollman (1934) reported that they were able to produce gout in turkeys by increasing the protein level of the diet to 40 per cent by the addition of horse meat. They were able to produce this effect also by the addition of 5 per cent urea to the diet. On the other hand, Patton (1939) reported that hens are able to tolerate large single doses of urea.

The injection of large amounts of glycine and of dl-alanine was found by Patton (1939) to be toxic when given to White Leghorn hens. Upon necropsy, the hens fed excess glycine revealed greatly enlarged kidneys which, upon histological examination, revealed indications of incipient necrosis. According to Patton, the evidence demonstrated conclusively that the kidneys are the chief site of glycine toxicity. Patton apparently did not observe an accumulation of urates in the tubules of the kidneys in this work.

Bird et al. (1946) found that a large percentage of the newly hatched chicks from hens receiving a diet deficient in animal protein consistently showed urate deposits in the kidneys and ureters. This condition was prevented by including sardine meal or cow manure in the breeding diet fed the hens. The preventive effects of these products was probably due to vitamin B_{12} content.

CARBOHYDRATES

Carbohydrates, along with fats, provide the energy needed by poultry for growth, maintenance, and reproduction. Carbohydrates, however, play a much more important role than fats in providing energy because they constitute a much larger proportion of the ration.

The nature of carbohydrates, Sugars, starches, dextrins, pentosans, and celluloses are the chief members of a group of organic compounds which are referred to as carbohydrates. All carbohydrates are composed of carbon, hydrogen, and oxygen, the latter two elements always being present in the ratio of two atoms of hydrogen to one atom of oxygen.

The sugars are the structural units from which all carbohydrates are formed. The simple 6-carbon sugars are known as monosaccharides; the more complex sugars, such as sucrose, maltose, and lactose, are known as disaccharides, while the starches and celluloses are composed of many glucose molecules and are therefore termed polysaccharides.

Digestion of carbohydrates. Only the simple sugars have sufficiently small molecular structures to gain entrance into the blood stream from the intestinal system. Therefore, all carbohydrates must be broken down into their simplest constituents before they are used in animal metabolism. The animal tissues secrete enzymes called amylases which split starches and dextrins in the lumen of the intestine into the disaccharide, maltose. Another enzyme, maltase, then breaks down maltose after absorption into the mucosal cells of the intestine into glucose, in which form the carbohydrate passes into the blood stream. Other specific enzymes in the digestive system act upon the other disaccharides,

breaking them down into their structural units, the simple sugars. Following passage into the portal vein, the simple sugars are carried to the liver where they are converted into glycogen. Then, as the demand arises in the body for energy, glycogen is broken down, releasing glucose to be carried by the blood to the site showing the demand. Thus glucose performs the major role in carbohydrate metabolism. When the glycogen stores become filled, the excess sugar resulting from carbohydrate digestion is readily converted into fat and is stored in the various fat depots throughout the animal body.

Cellulose and an accompanying compound, lignin, which together make up the cell wall structure of plants, are not acted upon by any enzyme secreted by animal tissues but can be broken down by certain bacteria. Unlike the ruminant which fosters a host of cellulose-splitting microorganisms within its rumen, the chicken is almost totally unable to derive any benefit from cellulose. The enzymes of the digestive tract of the chicken appear, however, to be as efficient as those of any other animal in breaking down starch and dextrins, provided, of course, that these nutrients are not enveloped by a cellulose membrane which protects them from the action of the digestive juices. Such a condition as this appears to exist in certain feedstuffs such as wheat bran, thereby greatly lowering the available energy content of these feeds as compared with other feeds containing equally as much cellulose but having the starch and sugar fractions accessible to digestion.

Chemical determination of carbohydrates. Nearly 100 years ago Henneberg and Stohmann (1860, 1865), of the Weende Experiment Station in Germany, realized that in order to formulate rations which contained adequate energy, they needed a chemical method for determining the indigestible portion of the carbohydrate fraction. The method which they devised is the one still used in most laboratories for determining the crude fiber content of a feed. In brief, the method entails digestion of the feedstuff first in dilute acid, then in dilute alkali, followed by a determination of the percentage of the feed remaining undissolved.

Since pentosans and lignins which cannot be digested by the chicken are slightly soluble in dilute acids and alkalies, this method does not give a true indication of digestibility, but it is useful because, on the whole, digestibility correlates rather well as an inverse function of the crude fiber content of the feed material.

In the chemical analysis of feeds, the carbohydrate portion is divided into two groups: crude fiber representing the indigestible portion and nitrogen-free extract, the supposedly digestible portion. The nitrogen-free extract contains the sugars and starch and small quantities of indigestible pentosans and lignins. It is determined by adding the moisture, protein, fat, ash, and fiber of a feed together and subtracting the sum from 100. In view of the many possibilities for variability in the composition of the nitrogen-free extract, it cannot be relied upon to give absolutely accurate values for the carbohydrate content of feedstuffs.

Cereals and cereal by-products. The cereal grains are universally recognized as our best sources of available energy-producing carbohydrate. The five most widely used cereals, corn, milo, wheat, barley, and oats, appear to rank in the order mentioned as sources of this nutrient. Experience has shown that the first three cereals can be interchanged at will, provided, of course, that the remainder of the diet is adequate in all nutrients other than carbohydrate. Oats and barley contain too much fiber to be used effectively as the sole source of carbohydrate. Removal of the oat hull, as is done in the manufacture of feeding rolled oats, results in a product having an energy content approximately equal to that of corn.

The by-products resulting from the processing of cereal grains are much inferior to the whole grains as sources of carbohydrate. This is due to the presence of portions of the outer coating of the

cereal grains, which are high in fiber and therefore low in digestibility, in practically all of the by-products. Fraps (1946), for example, has found that oat hulls contain no productive energy for the chick.

Milk and milk by-products. Since the most important carbohydrate in feedstuffs is starch, most feedstuffs can be evaluated as a source of carbohydrate by determining the starch content. An exception to this is found in the case of milk and milk by-products where the carbohydrate is present in the form of the disaccharide, lactose. Although the digestive system of the chicken contains an enzyme or enzymes for the splitting of lactose into its constituent monosaccharides, glucose and galactose, this hydrolysis appears to progress at a fairly slow rate.

Experience has shown that while small amounts, up to 10 per cent, of dried milk by-products have a definite beneficial effect upon growth of chicks, raising the level of lactose in the diet too high causes retarded growth. This effect is quite probably the result of two phenomena. First, the slow rate of hydrolysis of lactose reduces the uptake of sugar by the blood stream and thereby reduces the supply of available energy for growth. In addition, the presence of large amounts of unhydrolyzed lactose in the lower intestines and ceca stimulates the growth of acidophilic microorganisms (Hull and Rettger, 1917). The tremendous multiplication of these microorganisms upsets digestion in the lower intestine and produces a severe diarrhea which flushes out many of the nutrients which might otherwise be absorbed from this site.

FATS

Fats, like carbohydrates, are composed of carbon, hydrogen, and oxygen, and are used by the body as a source of energy. Since fats contain more carbon and hydrogen and less oxygen than do carbohydrates, they contain about 2.25 times as much energy per unit weight.

Digestion of fat. After ingestion, fats

are broken down by enzymes present in the intestinal juices into their constituent parts, the fatty acids and glycerol, in order to be absorbed through the intestinal wall. Some monoglycerides, obtained in the course of fat digestion, are absorbed, however, directly into the intestinal mucosal cells. These constituents, following absorption, are recombined into fat which is carried to all parts of the body by way of the lymph and the blood systems. Much of this fat is probably used directly as a source of energy. Any excess, however, is deposited within the cells of the body and in the fat depots underneath the skin, in the abdominal cavity, and around certain of the vital organs. Conclusive evidence that fatty acids may be converted to some extent into carbohydrates and later used to supply energy is still lacking, but glycerol may be converted into glucose and stored temporarily in the liver and muscle tissues as glycogen.

Special role of fat in poultry nutrition. In addition to serving as a source of energy, fat provides the unsaturated fatty acids, linoleic, linolenic, and arachidonic. These were found to be essential nutrients by Burr and Burr (1930), Burr et al. (1932), and Turpeinen (1938), in work with the rat. Reiser (1950) found that the chick is unable to synthesize linoleic and linolenic acids. Hopkins et al. (1960) and Machlin and Gordon (1961) showed that highly purified methyl linoleate stimulates chick growth. No effect was obtained by the former workers from methyl oleate and none from methyl linolenate by the latter. The quantity of linoleic acid required, however, is probably small under most conditions. Menge and Denton (1961) observed that edible coconut oil which contains little linoleic acid stimulated growth almost as well as equal quantities of corn oil or soybean oil in chicks, fed a simplified diet containing 0.5 per cent corn oil and soybean meal as the chief protein source. Russell et al. (1940) reported that a ration containing 0.1 per cent or less of dietary fat did not significantly retard the growth of

chicks up to 14 weeks of age when care was taken to provide the vitamins removed by the extraction procedure. On the other hand, some fat in the diet is highly desirable. Russell et al. (1942) showed that it aids in the absorption of the all-important fat-soluble vitamins.

Polyunsaturated fats such as corn oil, soybean oil, or safflower oil have been reported to increase egg size by Jensen et al. (1958), Hopkins and Nesheim (1962), and Marion and Edwards (1962). Increased hatchability of fertile eggs from the use of these fats has been reported by Machlin and Dudley (1962) and Marion and Edwards (1962). Shutze and Jensen (1963) obtained evidence that these effects are due chiefly to linoleic acid. The results of studies on the influence of polyunsaturated fats on egg production are conflicting.

Nonedible fats, particularly animal fats, are now used extensively in poultry rations largely because of favorable price resulting from the substitution of detergents for soap. The quantity usually added varies from 2.5 to 5 per cent.

Importance of antioxidants. The unsaturated fatty acids of fats, when not protected adequately by natural or synthetic antioxidants, first lose hydrogen, forming fatty acid-free radicals. Then, through uptake of oxygen, they are converted into organic peroxides which eventually break down into ketones and aldehydes, giving rancid fat its characteristic odor. According to Matill (1927) and Smith (1939) the peroxides may destroy the vitamin E and vitamin A activity of the feed, thereby producing a deficiency of these vitamins even though they were present in ample amounts at the time the feed left the manufacturer. More recent evidence by Miller et al. (1955) indicates that the destructive substance formed in unsaturated fatty acids is the free radical formed by abstraction of hydrogen. This in turn abstracts hydrogen from vitamin E, eventually converting it to the inactive quinone form. The destruction of vitamin A probably proceeds in the same manner but, for the most part, only after the vitamin E in the ration is destroyed. Thus, it is of importance, in the formulation of feed, to use ingredients which contain fat that has not started to become rancid. Vitamin E, which is present in many feedstuffs, is frequently added to poultry rations, is an effective antioxidant, but synthetic antioxidants are also used to prevent the initiation of fatty-acid oxidation. The mineral element selenium which can at least partially take the place of vitamin E in metabolism probably also functions for the most part as an antioxidant. Most of the natural carriers of fat contain unknown antioxidants which are sufficient to protect the fat for a considerable period of time, provided they have not been destroyed by heat or lost in some other way during the processing of the material.

ENERGY

Of the various nutrients needed for growth and production, the requirement for energy is by far the largest. Until recently, however, major attention in feeding poultry was given to the requirements for protein, amino acids, minerals, and vitamins, rather than energy needs. This has been due in part to the fact that a deficiency of energy in a poultry ration does not in general produce definite symptoms of deficiency other than lowered growth and reduced efficiency of feed utilization.

Robertson et al. (1948) presented results which indicated that White Leghorn chicks, for satisfactory growth, required a ration containing approximately 800 kcal. of productive energy per pound of feed. Panda and Combs (1950) obtained evidence which indicated that 850 kcal. per pound of ration were sufficient to promote rapid growth in New Hampshire chicks. The high energy ration reported by Scott et al. (1947) contained about 1,000 kcal. per pound of ration. Hill and Dansky (1954) found that maximum growth in Red Rock crossbred chicks, as determined by weight, was obtained on feeding rations containing as little as 625 kcal. per pound when the

low calorie content was obtained by diluting the ration with pulverized oat hulls. The greatest fat deposition in the bodies of the chicks was obtained, however, when the undiluted ration containing 970 kcal. per pound was fed. The carcass fat, dry basis, of the broilers fed this ration was 26.8 per cent, while the fat content of broilers fed a ration containing 858 kcal. of productive energy per pound was 23.2 per cent. Since this does not appear to be low enough to have any material effect on the quality of the carcass, the productive energy requirement of broilers appears to vary from approximately 850 to 1,000 kcal. per pound. These values on converting to metabolizable energy become 1270 kcal. to 1490 kcal. per pound respectively. At lower productive energy levels the fat content of the carcass was depressed, apparently because the chicks were unable to consume sufficient feed. Such rations, however, are satisfactory for the production of pullets for flock replacement since high fat content of the carcass is not a criterion of pullet quality.

The quantity of metabolizable energy required for egg production has been reported by Hill (1958) to be approximately 350 kcal. per hen per day with rate of lay at 70 per cent. Since the feed requirement for each 10 per cent change in egg production has been estimated by Byerly (1911) to be 0.014–0.015 pounds per hen per day, the change in the daily metabolizable energy requirement for each 10 per cent change in production is approximately 20 kcal., when the diet contains approximately 1350 kcal. per pound. Thus a hen laying at the rate of 90 per cent requires about 390 kcal. per day and one laying at the rate of 50 per cent about 310 kcal.

MINERAL ELEMENTS

The essential mineral elements are as important in the maintenance of the life, well-being, and production of poultry as amino acids and vitamins. They enter into the composition of the bones and give the skeleton, the bony framework of the body, the rigidity and strength needed to support the soft tissues. Minerals combine with protein, lipids, and other substances which make up the soft tissues of the body. They take part in the maintenance of osmotic pressure and the acid-base balance and exert specific effects on the ability of muscles and nerves to respond to stimuli. Minerals are also necessary for the activation of many of the enzymes present in the body.

Essential minerals. The mineral elements which have been found essential for the maintenance of animal well-being are calcium, chlorine, magnesium, phosphorus, potassium, and sodium, and the trace elements, cobalt, copper, iodine, iron, manganese, molybdenum, selenium, sulfur, and zinc. Cobalt is an essential element for ruminants, but the work of Davis et al. (1953) indicates that as long as the diet is adequate in vitamin B_{12}, it is unnecessary for poultry. Fluorine in small amounts is a constant constituent of several tissues, particularly bones. Evidence has been obtained that traces of this element may be essential, or at least beneficial, for some species, but no direct evidence to this effect has been obtained with poultry. The analyses of the individual mineral constituents in the body of mature chickens conducted by Halnan (1936) show that the major portion of the calcium, magnesium, and phosphorus of the body is present in the bones. Chlorine, iron, potassium, sodium, and sulfur, on the other hand, are largely present in muscles, other soft tissues, and body fluids.

Minerals in feedstuffs. The feedstuffs of plant origin are low in chlorine and sodium and, with the exception of alfalfa meal, also low in calcium. They contain relatively large amounts of potassium and reasonable quantities of magnesium and phosphorus. Corn and the feedstuffs of animal origin are low in manganese. With this exception and, in the case of milk products, also iron and copper, the feedstuffs of animal origin are reasonably well supplied with minerals. It is necessary, however, to supplement poultry rations

with additional sodium and chlorine in the form of salt, additional calcium, and, in many instances, phosphorus, zinc, and manganese. Because of the use of large amounts of soybean meal in present-day poultry rations, supplementation with additional iodine is usually indicated, unless large quantities of fish by-products are included in the ration, owing to the fact that soybeans have goitrogenic properties (Wilgus et al., 1941a). This is usually supplied by the use of iodized salt.

Calcium and phosphorus. Calcium and phosphorus are discussed together because of their close association in metabolism, particularly in the formation of bone. In the growing chicken, the major portion of the calcium in the ration is used for bone formation, while in the mature fowl the major portion is used for eggshell formation. Calcium is also essential for clotting of the blood, is required along with sodium and potassium for the normal beating of the heart, and is concerned in the maintenance of acid-base equilibrium.

In addition to its role in bone formation, phosphorus exercises important functions in the metabolism of carbohydrates and fats; it enters into the composition of important constituents of all living cells; and salts formed from it play an important part in the maintenance of the acid-base balance. It is apparently also concerned in calcium transport in egg formation.

The utilization of calcium and phosphorus is dependent upon the presence of an adequate amount of vitamin D in the ration. In vitamin D deficiency the amount of calcium and phosphorus deposited in the bones of growing chicks is reduced and the quantity of calcium in eggshells decreased. If the deficiency is greatly prolonged, these elements may even be withdrawn from the bones of growing chickens and mature fowls.

The quantity of calcium and phosphorus required by poultry is dependent to some extent upon the level of vitamin D supplied in the ration. When large amounts of vitamin D are fed, the amount of calcium and phosphorus in the ration may be reduced. On the other hand, a deficiency of vitamin D can be offset to a considerable extent by increasing the quantity of calcium and phosphorus.

The ratio of calcium to phosphorus in poultry rations may be varied over a fairly wide range without serious harm. However, when either element is present in large excess, it interferes with the absorption of the other from the digestive tract. For the growing chick the most desirable ratio appears to lie between 1.5:1 and 2:1. For laying hens the ratio is considerably wider due to their higher requirement for calcium.

All of the common sources of calcium and most of the sources of phosphorus used in feeding poultry appear to be well utilized. The utilization of the phosphorus in feedstuffs of vegetable origin, however, is dependent in part upon the character of the vitamin D included in the ration. The phosphorus in these feedstuffs is largely in the form of phytin. Singsen et al. (1947) showed that pure vitamin D_3 is more effective in making the phosphorus of phytin available than is the vitamin D present in cod liver oil. When phytin was fed to chicks as the only source of phosphorus in a purified diet, Gillis et al. (1949) found that it provided little, if any, available phosphorus, although the vitamin D content of the diet was in excess of the requirement under ordinary conditions. In work with hens, Common (1940) observed that approximately 75 per cent of the phytic acid of the diet was recovered in the droppings. Gillis et al; (1953) concluded that only about 50 per cent of the phosphorus of phytic acid was available to hens, fed either a purified or a practical diet. McGinnis et al. (1944) reported that more than 16 times as much vitamin D is required to promote normal bone development in chicks when the phosphorus is supplied entirely by means of feedstuffs of vegetable origin than when supplied by equivalent amounts in a purified diet by means of inorganic salts.

According to the results of McGinnis et al. (1944) and Singsen et al. (1947), it

seems probable that some of the phosphorus of phytin is available when supplied by means of natural products. Such products contain an enzyme called "phytase" which hydrolyzes phytin and sets the phosphorus free. However, McGinnis (1944) found that the presence of phytase in natural products does not increase the availability of phytin phosphorus, since no better results were obtained with wheat bran, an excellent source of phytase, than with autoclaved wheat bran in which the enzyme was destroyed.

The minimum calcium requirement of growing chicks was reported to be between 0.66 and 0.86 per cent of the ration by Bethke et al. (1929a), about 0.71 to 0.75 per cent by Hart et al. (1930), and approximately 0.66 per cent by Wilgus (1931). The minimum calcium requirement of chicks appears, therefore, to be approximately 0.7 per cent.

The minimum phosphorus requirement of growing chicks was reported by Bethke et al. (1929b) to be between 0.37 and 0.6 per cent, by Hart et al. (1930) about 0.3 to 0.42 per cent, by Wilgus (1931) 0.5 per cent or less, by Supplee (1935) between 0.26 and 0.5 per cent, and by Watkins and Mitchell (1936) less than 0.5 per cent. More recently, Gillis et al. (1949) found that 0.4 per cent of readily available phosphorus promotes normal bone formation and good growth in young chicks. Therefore, the minimum phosphorus requirement of chicks appears to be approximately 0.4 per cent. In order to get satisfactory bone development at this level, however, the phosphorus must be present in the ration in a highly available form.

The calcium and phosphorus requirements of chicks given in the NAS-NRC "Nutrient Requirements for Poultry" (1960b) are 1.0 per cent and 0.6 per cent, respectively (Table 6.2). The requirements, in addition, specify that the ration must contain at least 0.45 per cent phosphorus in the inorganic form so that not all of the phosphorus in the ration is supplied by means of feedstuffs of vegetable origin.

Norris et al. (1934) found that 1.81 per cent of calcium was sufficient to meet the requirements of laying hens as judged by egg production, eggshell strength, eggshell ash, and the levels of calcium and phosphorus in the blood. At this level of calcium, average egg production of 56 gm. eggs in two experiments varying in length from 44 to 48 weeks was approximately 56 per cent, eggshell calcium per egg was 2.09 gm. and eggshell breaking strength 4.09 kg. These values were not increased by raising the calcium content of the diet to 2.13 per cent. Blood calcium was also maximal at 1.81 per cent calcium. In this work, when 3.33 per cent of calcium was included in the ration, a decrease in egg production was obtained and the hens failed to maintain their weight as well as those fed somewhat lower levels of calcium. Gutkowska and Parkhurst (1942) reported that a ration containing 3.9 per cent calcium affected egg production detrimentally, but not hatchability and fertility. The phosphorus content of the ration used in the investigation was 0.75 per cent. Titus et al. (1937), on the other hand, found that levels of calcium varying from 4.05 to 5.4 per cent brought about a decrease in hatchability as well as egg production. Norris et al. (1934) used oystershell flour as the chief source of calcium in their experimental work; Gutkowska and Parkhurst (1942), pulverized calcite; and Titus et al. (1937), ground limestone and gypsum.

Evans et al. (1944b), who studied the calcium and phosphorus requirements of White Leghorn pullets kept in laying cages showed that the best egg production was obtained when the pullets received 2.5 per cent calcium. The duration of this experiment was 16 weeks. In a second experiment of 40 weeks' duration egg production and egg weight at 2.5 per cent calcium were equal to the results obtained with 3.0 per cent and 3.5 per cent calcium and eggshell smoothness tended to be better. Eggshell weight and shell thickness, however, were greater at the higher amounts of calcium. In this experiment egg weight was

somewhat greater than that obtained by Norris *et al.* (1954). This may explain partially the higher calcium requirement reported by Evans *et al.* (1944b). Since oyster shells rather than oystershell flour were used as the source of calcium in their experiments, it is probable also that the oyster shells were used less efficiently because of large particle size.

In the work by Norris *et al.* (1934) the percentage utilization of calcium for eggshell formation was 61.9 per cent when the diet contained 1.81 per cent, the quantity found to be optimum under the experimental conditions. This is in excellent agreement with the percentage retention of approximately 60 per cent observed by Hurwitz and Griminger (1960) in hens fed a diet containing 2.7 per cent calcium. These hens laid eggs, averaging 59.8 gm., at a rate of 77.0 per cent for 44 weeks. Since little calcium is stored by mature, heavily laying hens, percentage calcium retention and percentage utilization for eggshell formation are very nearly identical.

The amount of calcium in the shell of a 58–60 gm. egg is about 2.2 gm. At 60 per cent utilization for eggshell formation, the quantity of calcium which must be ingested per hen per day can be calculated from the rate of lay. This is about 1.83 gm. for 50 per cent production, 2.57 gm. for 70 per cent, and 3.30 gm. for 90 per cent. The calcium content of rations of medium energy content, designed to meet the needs of hens averaging 4.5 pounds at the end of the first production cycle, can be estimated from data reported by Byerly (1941). Such rations should contain 1.8 per cent calcium for an egg production rate of approximately 50 per cent, 2.25 per cent for 70 per cent production, and 2.75 per cent for 90 per cent production. Slightly larger amounts will be required in rations of high-energy content containing added fat, or in rations fed to hens of lower final average weight than 4.5 pounds.

Norris *et al.* (1934), using a ration containing 1.8 per cent calcium, found that the minimum phosphorus requirement of laying hens was 0.75 per cent of the diet. Miller and Bearse (1934), with rations varying in calcium from 2.23 to 3.03 per cent, obtained the highest egg production with 0.8 per cent phosphorus. Evans *et al.* (1944a) obtained higher egg production with 0.8 per cent phosphorus in the ration of laying hens than when 0.6 per cent was supplied. The calculated available phosphorus content of the diets used by the research workers which revealed minimum requirements were 0.45–0.50 per cent, 0.50–0.60 per cent, and 0.45–0.50 per cent respectively. Gillis *et al.* (1953) reported that hens confined on wire-mesh floors for experimental periods up to 35 weeks required 0.5 per cent available phosphorus for maintenance of weight and egg production and 0.6 per cent for optimum blood phosphorus level and prevention of bone decalcification. Singsen *et al.* (1962) showed that hens confined on wire-mesh floors for 40 weeks required more than 0.35 per cent available phosphorus but not more than 0.55 per cent for egg production. Hatchability of fertile eggs and percentage of bone ash, however, were satisfactory at the smaller amount.

An exceptionally high phosphorus turnover is a characteristic of the rapidly laying hen. Not only is the excretion of phosphorus through the usual channels increased but, in addition, appreciable amounts are deposited in the egg. Phosphorus is found in the egg yolk as a constituent of lecithin and vitellin. Phosphorus is also concerned indirectly in eggshell formation although it comprises less than 1 per cent of the shell. Norris *et al.* (1933) found that egg production per hen was not only decreased when the phosphorus content of the diet was 0.5 per cent, but also that the amount of ash in the eggshell was decreased. Halnan (1925) pointed out that egg production is associated with increased phosphorus catabolism, and that during egg production the phosphorus lost from the body is much greater than that contained in the eggs laid. Halnan's observations were confirmed by Common

(1932), who found that egg production was correlated with relatively heavy excretion of phosphorus in the feces.

The calcium requirement of laying hens given in the NAS-NRC "Nutrient Requirements for Poultry" (1960b) is 2.75 per cent of the ration and the phosphorus requirement 0.6 per cent (Table 6.2).

Mussehl and Ackerson (1935) found that to obtain maximum growth and maximum bone ash in turkey poults, levels of calcium varying from 1.45 to 1.98 per cent and levels of phosphorus varying from 0.63 to 1.02 per cent were required in a ration containing 1.0 per cent of cod liver oil. Motzok and Slinger (1948) presented evidence which indicated that turkey poults fed a high-energy ration required minimum levels of 1.3 to 1.6 per cent calcium and 0.7 to 0.9 per cent phosphorus. Hammond et al. (1944) reported that 1.0 per cent calcium and 0.6 per cent phosphorus are adequate for growing turkeys and that under favorable conditions as little as 0.5 per cent phosphorus may be fed without detrimental effect. Singsen et al. (1947) showed that 0.65 per cent nonceral phosphorus promoted satisfactory growth and bone formation in turkey poults and that 0.4 per cent was adequate, provided the diet contained not less than 0.65 per cent total phosphorus. Wilcox et al. (1955) obtained results indicating that the phosphorus requirement of turkey poults fed a practical ration was 1.0 per cent, when approximately 0.45 per cent was phytin phosphorus and the remainder inorganic. No studies appear to have been conducted on the calcium and phosphorus requirements of breeding turkeys.

The calcium requirements of turkey poults given in the NAS-NRC "Nutrient Requirements for Poultry" (1960b) is 2.0 per cent of the ration and the phosphorus requirement is 1.0 per cent (Table 6.3). The calcium and phosphorus requirements given in the report for breeding turkeys are 2.25 and 0.75 per cent of the ration, respectively, in spite of the lack of experimental evidence. These requirements are based, presumably, upon the fact that breeding chicken rations have promoted satisfactory egg production in breeding turkeys. The NAS-NRC requirements also specify that the ration of starting poults contain 0.5 per cent inorganic phosphorus in order to have some highly available phosphorus in it.

Magnesium. Magnesium is closely associated with calcium and phosphorus in the body. It is essential for bone formation, about two-thirds of the magnesium in the body being present in the bone, chiefly as a carbonate. It is also necessary for carbohydrate metabolism and the activation of several enzymes. Eggshells contain about 1.4 per cent magnesium.

Magnesium is present in sufficient amounts in ordinary feedstuffs so that practical poultry rations contain in general enough to meet the requirement. It is possible, however, to formulate rations which contain excess magnesium, with the result that detrimental effects are produced. Buckner et al. (1932) found that the addition of magnesium carbonate to chick rations in amounts sufficient to raise the magnesium level from 0.76 to 7.05 per cent upset the calcium and phosphorus balance, resulting in deformed bones with low ash and calcium content. A similar effect on bone ash has been reported by Mussehl et al. (1930), while Schaible et al. (1963) obtained perosis with magnesium carbonate additions. Alder (1927) found that feeding dolomite limestone containing a high percentage of magnesium for a period of four months caused egg production to decrease and the shells of the eggs to become progressively thinner. Nearly every hen in the dolomite pen developed diarrhea as indicated by the droppings and badly soiled condition of the feathers on the abdomen. The hens also became extremely irritable and easily frightened. All of these conditions cleared up within a short time after substituting a high-grade limestone for the dolomite. Work with several species of animals, however, indicates that magnesium is less

harmful when the ration contains liberal amounts of calcium and phosphorus than when these elements are fed at a marginal level.

Almquist (1942) found that the magnesium requirement of the chick is approximately 0.04 per cent during the first few weeks of life. Almquist observed that the chicks fed the basal ration grew slowly for approximately one week, then ceased growing and became lethargic. When disturbed, these chicks frequently passed into a brief convulsion accompanied by gasping and finally into a comatose state sometimes ending in death. Gardiner et al. (1959) reported that the magnesium requirement of the chick for maximum growth and prevention of deficiency symptoms is approximately 0.025 per cent. Using a purified diet containing 0.7 p.p.m. magnesium, McWard and Scott (1961) found the chick's magnesium requirement for good growth and survival is approximately 0.02 per cent. The best growth, however, was obtained at magnesium levels of 0.025 per cent to 0.045 per cent. Nugara and Edwards (1961) showed that the magnesium requirement of the chick is affected by the dietary levels of calcium and phosphorus. They found that, when the calcium content of the diet was 1.2 per cent and the phosphorus 0.6 per cent and 0.9 per cent, the magnesium requirement was 0.029 per cent and 0.042 per cent respectively. The higher values obtained by these investigators agree reasonably well with the magnesium requirement of the chick given in the NAS-NRC "Nutrient Requirements for Poultry" (1960b). This is 220 mg. per pound or 0.048 per cent.

The magnesium requirement of turkey poults fed a purified diet, was reported by Sullivan (1962) to be 216 mg. per pound or 0.0475 per cent. Keene and Combs (1962) obtained results which indicated that the poult, fed a purified diet containing an antibiotic, required 0.042 per cent magnesium. In work with chicks fed a purified diet, the inclusion of an antibiotic in the diet was found to decrease the chick's requirement for magnesium slightly. The magnesium deficiency symptoms of poults were observed to be similar to those of chicks Poults showed no evidence of toxicity when the diet contained 0.18 per cent magnesium.

Sodium and chlorine (salt). Sodium as chloride, carbonate, and phosphate is found chiefly in the blood and body fluids Sodium chloride is the chief inorganic constituent of the blood plasma, and is presumably the source of chlorine in the hydrochloric acid of the gastric juice Sodium is connected intimately with the regulation of the hydrogen ion concentration of the blood. Sodium, along with potassium and calcium in proper balance, is essential for heart activity.

The addition of salt to poultry mash mixtures is common practice and in most instances is probably necessary for optimum growth and production. Mitchell and Carman (1926) reported that chicks fed a cereal ration containing no added salt showed retarded growth with decreased efficiency of food utilization. They concluded that the retarded growth was due to a deficiency of sodium rather than of chlorine. These results have been confirmed by Prentice (1933a) and by Burns et al. (1953). Prentice (1933b) also reported that a lack of salt in the ration of laying hens resulted in decreased egg production and egg size, loss of weight, and cannibalism.

Sjollema (1935) and Halpin et al. (1934) obtained better growth in chicks when fed rations containing 0.5 and 1.0 per cent added salt. Burns et al. (1952) found that the minimum amount of salt required by hens fed a purified diet was approximately 0.2 per cent but suggested 0.5 per cent as an optimum amount to supply. Burns et al. (1953) reported that the minimum amount of chlorine required by chicks fed a purified ration is less than 0.06 per cent and the amount of sodium is between 0.1 and 0.3 per cent. These values correspond to 0.25–0.75 per cent salt. Leach and Nesheim (1963) observed that

chicks fed a purified diet containing 0.24 per cent sodium and 0.4 per cent potassium required 0.12 per cent chlorine.

Slinger et al. (1950) obtained evidence that maximum growth in chicks fed high-energy, low-fiber rations was obtained with 0.25 per cent or less of added salt but that the salt requirement was increased on including wheat by-products and cellulose in the ration. Heuser (1952) obtained maximum growth in chicks by supplementing a medium-energy ration already containing 0.4 per cent chlorides expressed as salt with 0.25 per cent salt. No further improvement in growth was observed with larger amounts of salt.

According to the NAS-NRC "Nutrient Requirements for Poultry" (1960b), 0.15 per cent of sodium should be adequate for all ages of chickens and turkeys. This is equivalent to 0.37 per cent sodium chloride. In view of the presence of some sodium in practical ingredients, the addition of 0.25 per cent salt is, however, usually sufficient. This represents added salt and not salt already present in the ingredients of the mash mixture. When the ration is composed of both mash and grain, the mash mixture should contain 0.5 per cent added salt in order to provide approximately 0.25 per cent in the entire ration. However, these recommendations may supply too much salt and lead to excess water consumption and wet litter when large amounts of animal products which contain considerable quantities of salt are included in the ration. Under these conditions it seems advisable to consider the salt already present in the ration and add enough to provide a total of approximately 0.37 per cent.

Excessive amounts of salt in the ration are toxic to chickens. Sufran (1909) found that the lethal dose is approximately 4 gm. per kilogram of body weight. Quigley and Waite (1932) fed chicks rations containing from 1.0 to 15.0 per cent salt and found that levels of 8.0 per cent or greater depressed growth. Mortality, however, was excessive above the 5.0

per cent level. These workers confirmed the observation of Suffran that the minimum lethal single dose is 4 gm. per kilogram of body weight. Barlow et al. (1948) fed day-old chicks graded amounts of salt in an all-mash ration to nine weeks of age and observed mortality of 18.8 per cent at the 3.0 per cent salt level and 34.4 per cent at the 4.0 per cent level. Young chicks were more susceptible to toxic effects of salt than older ones and water consumption increased with increase in the salt content of the ration. Mitchell et al. (1926b) found that chickens from 9 to 21 weeks of age could be fed as much as 8.0 per cent salt in the ration without any detrimental effects on their rate of growth and physical condition after the chickens became accustomed to the ration. Matterson et al. (1946) fed day-old turkey poults graded quantities of salt in an essentially salt-free diet for 23 days and observed 25 per cent edema and 25 per cent mortality at 4.0 per cent salt but none at 2.0 per cent. Roberts (1957) found that a ration containing 4.0 per cent salt did not affect either growth or food consumption in 8-week-old poults but water consumption was noticeably increased. In mature turkeys 8.0 per cent salt may have caused some reduction in gain but food consumption was not decreased. No mortality occurred in any of the experiments. Torrey and Graham (1935) reported that ducks are more susceptible to salt poisoning than chickens.

The symptoms of salt intoxication are inability to stand, intense thirst, pronounced muscular weakness, and convulsive movements preceding death. Postmortem examination has revealed lesions in many organs, but particularly hemorrhages and severe congestion in the gastrointestinal tract, muscles, liver, and lungs.

Potassium. Potassium is widely distributed in feedstuffs of both plant and animal origin, and although the requirement of poultry for this element is rather high, there seems but little likelihood of a defi-

ciency occurring in practical poultry rations.

Potassium, in contrast to sodium, is found primarily in the cells of the body rather than in the body fluids. The soft tissues of the fowl contain more than three times as much potassium as sodium. The sodium and potassium content of the bones are approximately the same. The fundamental role of potassium in metabolism is not well understood. It is necessary for normal heart activity where it exerts an effect opposite that of calcium, reducing the contractility of the heart muscle and favoring relaxation. Potassium ions also appear to increase membrane permeability.

Ben Dor (1941) reported that chicks deficient in potassium exhibit high mortality and retarded growth. He concluded that the chick requires 0.17 per cent potassium in the diet. Gillis (1948, 1950) observed that an interrelationship exists between potassium and phosphorus. He found that although 0.16 per cent potassium was sufficient to prevent mortality, 0.2 per cent potassium was required when the phosphorus level was 0.6 per cent, and 0.24 per cent potassium was needed when the phosphorus level was 0.55 per cent. Burns et al. (1953) reported that the potassium requirement of chicks was between 0.25 and 0.40 per cent, the higher level being required for maximum growth. Leach et al. (1959) obtained evidence that the minimum potassium requirement for rapid growth of chicks fed a high energy diet containing 0.68 per cent phosphorus is 0.3 per cent. Results obtained by Supplee and Combs (1960) indicate that the potassium requirement of turkey poults is approximately 0.6 per cent of the diet in the absence of an antibiotic and 0.45 per cent in the presence of one. The potassium requirement of starting chicks given in the NAS-NRC "Nutrient Requirements for Poultry" (1960b) is 0.2 per cent and that for growing chicks is 0.16 per cent (Table 6.2).

Manganese. Manganese is one of the so-called "trace elements" required in poul-

try. Wilgus et al. (1936, 1937a) reported that perosis in poultry is caused for the most part by manganese deficiency. They also showed that the perosis-preventing property of certain feedstuffs is correlated with their manganese content.

Perosis is an anatomical deformity of the leg bones of young chickens, turkeys, pheasants, grouse, and quail. The symptoms generally found are gross enlargement of the tibio-metatarsal joint, twisting or bending of the distal end of the tibia and of the proximal end of the metatarsus, and, finally, slipping of the gastrocnemius tendon from its condyles (Fig. 6.2). The latter symptom causes complete crippling in the affected leg, and if both legs are so affected, death usually results due to the inability of the chick to secure food and water. Early observers of perosis noted that it was most likely to occur under the crowded conditions of confinement rearing; that rations having a high mineral content tended to aggravate the condition; and that heavy breeds were more susceptible than light breeds.

The amount of manganese required by chicks varies with different breeds and strains. Wilgus et al. (1937a) reported that 55 p.p.m. was adequate for the cross-

FIG. 6.2 — An extreme case of perosis. The most common causative factor of this disease is manganese deficiency.

bred chicks used in their experiments. Insko et al. (1938) found 36 to 37 p.p.m. to be adequate for growth and the prevention of perosis in Rhode Island Red chicks. Gallup and Norris (1939a) reported that approximately 50 p.p.m were required by New Hampshire chicks, while 30 p.p.m. completely prevented the disorder in White Leghorn chicks. They also observed that 1,000 p.p.m. of manganese was not toxic to day-old chicks, kept on experiment to six weeks of age.

In addition to its perosis-preventing properties, manganese is necessary for the formation of normal bones. Wilgus et al. (1937b) observed that frequently the leg bones of chicks fed perosis-producing diets were thickened and shortened. Gallup and Norris (1938) reported that the leg bones of chicks fed a manganese-deficient diet were 7 or 8 per cent shorter than those of chicks of the same age, sex, and weight receiving adequate manganese. In a more extensive study, Caskey et al. (1939) reported that manganese deficiency in the diet of chicks resulted in a highly significant shortening of the bones of the legs and wings and also a shortening of the spinal column. They also found that the ash content of the bones of the deficient chicks was significantly lower than that of chicks fed an adequate diet.

The evidence that manganese is necessary for bone formation is supported by the observations of Wiese et al. (1939, 1941) that bone and blood phosphatase, as well as the ester phosphorus of the blood, are depressed in manganese deficiency in the chick. Combs et al. (1942) confirmed the observation that manganese deficiency lowers bone phosphatase. These results, together with those of Caskey et al. (1939), suggest that manganese deficiency causes a disproportionately greater retardation in the development of bones in chicks during growth than that of other tissues of the body. Creek et al. (1960) have shown, however, that the stress of the relatively greater weight of the soft tissues is not the primary cause of the bone malfor-

mation in perosis. After severing the Achilles tendon at the right hock joint at three days of age, these investigators observed that malformation of the bones of the immobilized leg developed but to a lesser extent than in the unoperated right leg of other chicks.

The need for manganese by mature fowls was demonstrated by Gallup and Norris (1937, 1939b), who reported that pullets fed a diet containing 13 p.p.m. manganese produced less than half the number of eggs laid by similar pullets fed a diet containing 200 p.p.m. In this work the manganese content of the eggs from the low-manganese group was reduced, fertility was slightly decreased, and the hatchability of eggs was markedly lowered by manganese deficiency. Embryos in the eggs of low-manganese content usually died during the final stages of incubation.

Lyons and Insko (1937) also found that manganese deficiency resulted in very low hatchability of fertile eggs and, in addition, observed the production of chondrodystrophy in the embryos. The peak of mortality for such embryos occurred on the twentieth and twenty-first days of incubation. The chondrodystrophic embryos were characterized by very short, thickened legs, short wings, "parrot beak," globular contour of head, protruding abdomen, and retarded down and body growth. Very marked edema was noted in about 75 per cent of these embryos. The manganese content of the eggs producing chondrodystrophic embryos was much smaller than that of normal eggs.

Caskey et al. (1944) reported that chicks hatched from eggs produced by hens fed a diet deficient in manganese sometimes exhibit ataxia, particularly when excited. This is a nervous disorder involving spasms in which the head may be drawn forward and bent underneath the body or retracted over the back. The ataxic chicks grew normally and reached maturity but failed to recover completely from the ataxia. Caskey and Norris (1940) observed that they also retained the short

bones characteristic of embryos and newly hatched chicks when the maternal diet is deficient in manganese.

Caskey and Norris (1938) reported that the breaking strength of the eggs from lots of hens receiving different levels of manganese increased as the quantity of manganese in the diet increased. The breaking strength averaged 6.6 pounds for a lot receiving 6.5 p.p.m. manganese and 9.3 pounds for a lot receiving 100 p.p.m. The ash content of the eggshell also increased with increase in the manganese content of the diet. Lyons (1939) described the effect of a low-manganese diet on the characteristics of eggshells. Eggs produced by hens fed a deficient diet showed large areas of poor calcification as indicated by differences in smoothness and translucency. A lowered breaking strength and a smaller percentage of shell were also found.

In studies on the manganese requirement of hens, Caskey and Norris (1938) concluded that 20 p.p.m. is sufficient for egg production and hatchability. The results of Schaible et al. (1938) indicated that additional manganese above 39 p.p.m. did not benefit fertility, hatchability, or egg production. Golding et al. (1940) found that heavy breeds require more manganese than light breeds. The work with hens, therefore, supports the results obtained with chicks. Golding et al. (1940) also found that 9 p.p.m. of dietary manganese were adequate for hatchability and the prevention of chondrodystrophy but not for egg production in White Leghorn pullets. This amount of manganese, however, was not sufficient for hatchability in Barred Plymouth Rocks. Couch et al. (1947) obtained evidence which indicated that the manganese requirement of hens in their second year of production is greater than that of pullets. These workers also reported that high levels of manganese in the diet lower the vitamin D requirement.

According to the work of Schaible et al. (1938), manganous sulfate, manganous chloride, manganous carbonate, potassium permanganate, and manganese dioxide appeared to be equally satisfactory sources of manganese for use in poultry rations. Oxide ores of manganese, such as manganite and pyrolusite, were comparable to the foregoing compounds; but the carbonate ore, rhodochrosite, and the silicate ore, rhodonite, were not satisfactory.

Although high concentrations of manganese are poisonous, the amounts used in practice are much below the toxic level. More than thirty to forty times the amounts required were fed by Gallup and Norris (1939a) without apparent harm.

According to the NAS-NRC "Nutrient Requirements for Poultry" (1960b), chicks and poults should receive 25 mg. per pound of ration and hens and turkey breeders 15 mg. per pound. This is usually supplied by including in the ration 6 to 8 ounces of a feed grade of manganese sulfate containing about 70 per cent of the pure compound.

Iodine. Traces of iodine are required for normal functioning of the thyroid gland in poultry as well as all other animals. Most of the iodine in the body is held by the thyroid which has a remarkable affinity for this element. Thyroxin, the hormone secreted by the thyroid, contains approximately 65 per cent iodine and acts as an important regulating agent in body metabolism. When the intake of iodine is suboptimal, the thyroid tissue enlarges and the condition known as goiter results

The problem of iodine deficiency is confined to areas in which the soil, and consequently the water and feed crops, contain insufficient amounts of this mineral. In the United States these areas are primarily in the Northwest and in the Great Lakes region, but many other sections are either marginal or actually deficient in this respect. To some extent iodine deficiency in poultry has probably been offset by the widespread use of fish meal, oyster shells, and fish oils which contain significant amounts of iodine. Nevertheless, goiter has been described in poultry

by a number of investigators. Welch (1928) reported that goiter occurred frequently in poultry in Montana. He minimized, however, the effect of this condition on the general health and productivity of the affected birds. Wilgus et al. (1941a) observed that soybeans in the diet of poultry have a goitrogenic effect. They found that this effect is partially inactivated by heat, however, and that iodine is a counteractant. Soybean meal was also found to be goitrogenic, but no detrimental effects other than that on the thyroid gland were noted in its use in feeding growing chickens.

Patton et al. (1939), Wilgus et al. (1941b), and Gassner and Wilgus (1940) reported that iodine deficiency results in enlarged thyroids and in some cases lower body weight in growing chicks. They estimated that the growing chicken requires 1 p.p.m. of iodine in the diet for optimum growth and the prevention of goiter. They observed congenital goiter in baby chicks hatched from hens receiving 0.025 p.p.m. of iodine in the ration. By using more reliable procedures for determining iodine, Godfrey et al. (1953) found that the iodine requirement of chicks is between 0.03 p.p.m and 0.15 p.p.m. Later, Creek et al. (1957) reported that 0.05 p.p.m. or less failed to support normal growth while 0.075 p.p m. was sufficient. Larger amounts, however, were required for normal thyroid histology, since abnormalities were prevented only when the level was as high as 0.40 p.p.m. The inclusion of 4.8 p.p.m. of iodine in the diet in preliminary studies was not found to be toxic.

The results of studies on the iodine requirement of breeding hens by Rogler et al. (1961) showed that hatchability of the eggs of hens fed a ration containing 0.010–0.024 p p m. of iodine was greatly reduced and hatching time delayed 2 to 2.5 days. Embryonic development except for thyroid size appeared normal, however, when the iodine level was increased to 0.035 p.p.m. At 0.125 p.p.m. of iodine thyroid size became essentially the same as when the diet of the hens contained 0.5 p.p.m.

The results of these workers indicate that the use of 0.5 per cent iodized salt in chick rations should prevent the development of iodine deficiency, since this would supply 0.35 p.p.m. in addition to that contained in the diet. In the NAS-NRC "Nutrient Requirements for Poultry" (1960b) the iodine requirement of chicks and breeders is estimated to be 0.5 mg. per pound and that of growing chicks and layers to be 0.2 mg. per pound.

Iron and copper. Both iron and copper are necessary for hemoglobin formation. Iron is present in heme, the iron porphyrin nucleus of hemoglobin. This nucleus is also one of the components of the cytochromes and the enzymes, peroxidase and catalase. Copper also takes part in the activity of several enzymes, but, while essential for hemoglobin formation, does not enter into its composition. In the absence of copper, dietary iron is absorbed and deposited in the liver and elsewhere, but hemoglobin formation does not occur, and anemia results. Elvehjem et al. (1929) showed that both iron and copper are required for hemoglobin synthesis in the chick. Hill and Matrone (1961) concluded from the results of several experiments that the chick needed approximately 40 p.p.m. of iron and 4 p.p.m. of copper for maximum hemoglobin formation (Fig. 6.3). Davis et al. (1962) presented evidence which indicated that the iron requirement of the chick was approximately 65 p.p.m. when the diet contained 10 p.p.m. of copper.

The demand for iron and copper for egg formation is large, as the average egg contains about 1.1 mg. of iron and 0.067 mg. copper. The results of several investigators indicate, however, that the addition of extra iron and copper to practical laying rations does not increase the iron and copper content of the eggs, although Erikson et al. (1933) found that hens with access to sunshine and bluegrass
FIG. 6.3 — Deficient pigment formation in the feathers of a New Hampshire chick resulting from a shortage of dietary iron. The chick was also anemic.

range, produced eggs with higher iron and copper content than hens confined indoors.

The hemoglobin level of the blood of hens has been observed to fall with the beginning of egg production, but this does not appear to be related to the iron and copper content of the diet. In view of the fact that the hemoglobin level rises rapidly with the onset of broodiness, it appears more probable that the low hemoglobin levels which prevail in egg production are due to changes in the hormone mechanisms of the body rather than to iron and copper deficiencies.

Mayo et al. (1956) studied the copper tolerance of young chicks using growth, mortality, and occurrence of muscular dystrophy as indications of copper tolerance. In one experiment, 324 p.p.m. of copper caused significant retardation of growth at four weeks of age, and in a second experiment, 520 p.p.m. decreased growth at this age, but the males equalled the weight of the control lot when eight weeks of age. A marked increase in mortality occurred when the diet contained 1,270 p.p.m. of copper. The estimated iron and copper requirements of the chick given in the NAS-NRC "Nutrient Requirements for Poultry" (1960b), are respectively 20 and 2 p.p.m.

Sulfur. The amino acids, methionine and cystine, which contain sulfur in organic combination, supply practically all the sulfur utilized by poultry. Traces, however, are also supplied by the vitamins, thiamin and biotin, and by inorganic sulfates. Work by Machlin (1955) as well as by Gordon and Sizer (1955) indicates that the chick has a requirement for sulfur which may be satisfied either by providing methionine and cystine in excess of that required for protein formation, or by means of sulfates. When the methionine and cystine content of the diet was somewhat deficient, sulfate was found to exert a sparing effect on these amino acids.

With adequate quantities of methionine and cystine in the diet, all the other sulfur-containing compounds in the body appear to be derived from the catabolism of these amino acids. In studies on the sulfur content of egg yolk and egg white, Marlowe and King (1936) found that all of the sulfur in these products was organically bound, and also that nearly all could be accounted for by the cystine and methionine sulfur.

Zinc. Traces of zinc appear to be necessary for life in all animals. It is a constituent of the enzyme carbonic anhydrase and appears necessary for the activation of several enzymes. O'Dell and Savage (1957a, 1957b) reported significant increases in the growth of chicks fed a purified soybean protein diet containing 15 to 20 p.p.m. of zinc by supplementing the diet with 100 p.p.m. of this mineral. Zeigler et al. (1958) observed zinc deficiency in chicks supplied demineralized water and either a purified soybean protein diet or a purified casein diet containing respectively 9 and 4.2 p.p.m. of zinc. The gross deficiency symptoms were retarded growth, poor feathering, enlarged hocks, and scaling of the skin, particularly on the feet. These symptoms were obtained only when the galvanized feeders and waterers were replaced with stainless steel ones, the galvanized battery cages coated with plastic resin, and the diets

stored in tin cans. Without these changes, little evidence of deficiency was obtained. Increasing the calcium content of the diet from 1.23 per cent to 2.07 per cent enhanced the severity of some of the symptoms. Similar observations have been reported by Edwards et al. (1958).

On feeding graded quantities of zinc to chicks Zeigler et al. (1961) found that the requirement was 12–14 p.p.m., when a purified diet containing casein was fed and 27–29 p.p.m., when the diet contained isolated soybean protein. Davis et al. (1962) reported that chicks fed a diet containing isolated soybean protein required 43 p.p.m. of zinc for maximum growth and bone formation. Evidence was obtained by Kratzer et al. (1959) that the turkey poult required approximately 60 p.p.m. of zinc when supplied a diet containing isolated soybean protein. The requirement was greatly reduced by including the chelating agent, ethylenediaminetetraacetic acid, in the diet. This finding was confirmed by Davis et al. (1962), using chicks as the experimental subjects. In the work by Zeigler et al. (1961) 1,000 p.p.m. of zinc appeared to depress the growth of chicks at 26 days of age slightly but did not increase mortality. The estimated zinc requirements of chicks and turkey poults, given in the NAS-NRC "Nutrient Requirements for Poultry" (1960b) are 45 p.p.m. and 55 p.p.m., respectively (Fig. 6.4).

Fluorine. No satisfactory evidence that fluorine is an essential mineral has yet been obtained. McClendon and Gershon-Cohen (1953) reported retarded growth and increase in dental caries in rats from fluorine deficiency but no one yet has been able to confirm these results. The value of adding 1.0–1.2 p.p.m. of fluorine to the drinking water for the prevention of dental caries in children, however, has been demonstrated.

When appreciable quantities of fluorine are ingested by animals, harmful effects result. These may not be revealed immediately as the toxic effects of fluorine are

FIG. 6.4 — Enlarged hocks in a turkey poult caused by zinc deficiency.

cumulative. The fluorine tolerance of chickens seems to be definitely higher than that of other species of farm animals.

Halpin and Lamb (1932) showed that the toxic level of fluorine in the rations of chickens is between 0.035 and 0.070 per cent. Excess fluorine resulted in retarded growth in young chicks and in lower egg production and loss of weight in laying hens. On the other hand, Hauck et al. (1933) obtained evidence that the toxic level of fluorine, as measured by the growth of chicks, lies between 0.068 and 0.136 per cent. Kick et al. (1933) reported that the toxic level is between 0.036 and 0.072 per cent. On feeding graded levels of fluorine to turkey poults eight weeks of age, Anderson et al. (1955) found that up to 400 p.p.m. did not affect weight gains, feed consumption, or feed efficiency during the subsequent eight weeks.

The Association of American Feed Control Officials (1953) has recommended

that the fluorine content of minerals or mineral mixtures used in poultry feedstuffs contain not more than 0.60 per cent of fluorine, and that the total fluorine content of poultry rations should not exceed 0.035 per cent. The Subcommittee on Fluorosis Problems of the NAS-NRC Committee on Animal Nutrition (NAS-NRC, 1960a) has suggested that the level of fluorine be limited to 0.015–0.03 per cent of the ration for chickens, and 0.03–0.04 per cent for turkeys when the fluorine is supplied by soluble fluorides. The quantity in chicken rations may be increased to 0.03–0.04 per cent when the fluorine is supplied by phosphatic limestone or rock phosphate.

The fluorine hazard in poultry feeding, outside of certain local areas, is related largely to the use of fluorine-containing mineral supplements. These minerals are the different varieties of phosphate rock, the superphosphates produced from them, and the phosphatic limestones. Raw rock phosphates ordinarily contain from 3.25 to 4.0 per cent fluorine, while superphosphate and phosphatic limestone usually contain appreciably less. Heat treatment of the raw rock phosphate or superphosphate is employed to remove the fluorine from these products. Commercially defluorinated phosphate rock and superphosphate as now marketed generally contain as little as 0.02 to 0.03 per cent of fluorine and come well within the limits of permissible fluorine content.

Selenium. Selenium has been shown to be an essential mineral element for the chick in work conducted independently by Scott et al. (1957) and Patterson et al. (1957). Selenium was found to prevent the development of exudative diathesis in chicks fed a Torula yeast diet deficient in vitamin E. Under these conditions Patterson et al. reported that as little as 0.3 p.p.m. of selenium gave complete protection against exudative diathesis, while Scott et al. observed that a level of 0.1 p.p.m. was effective in preventing the development of this syndrome

Norris et al. (1957) reported that no growth stimulation or other effects from selenium were obtained in chicks fed a purified soybean protein diet containing adequate amounts of vitamin E. Because of these findings, the inclusion of selenium in chick rations seems unnecessary and perhaps undesirable in view of evidence obtained by Poley et al. (1941) and Carlson et al. (1954) that 10 or more p.p.m. is toxic for the chick.

This quantity of selenium is also toxic to breeders. Poley and Moxon (1938) fed laying rations containing 2.5, 5.0, and 10.0 p.p.m. of selenium. At the intermediate level, hatchability was not appreciably affected but some chicks had wiry down. The high level, however, reduced the hatchability to zero, the dead embryos showing short upper beaks, edema of head and neck, missing toes and eyes, wiry down, and other characteristics of selenium poisoning. No effects on body weight, egg production, or fertility were observed. Moxon and Poley (1938) showed that the selenium content of the body of hens and of eggs increased proportionally to the amount in the ration.

Molybdenum. Higgins et al. (1956) obtained evidence, by resorting to the use of tungsten as a molybdenum antagonist, that this mineral element is required for the growth of chicks as well as for the maintenance of the xanthine oxidase content of chick tissues. Reid et al. (1956) also reported that molybdenum stimulates growth of chicks and poults. Purified diets were used in the experimental work of these investigators. Norris et al. (1957) and Leach et al. (1962) confirmed the results of Higgins et al. (1956) using tungsten as an antagonist. Without the inclusion of tungsten in the purified diet, a significant growth increase of 6.1 per cent was obtained by adding molybdenum to a chick diet containing isolated soybean protein and 4.8 p.p.m. of zinc. Increasing the zinc to 64.8 p.p.m. or replacing the isolated soybean protein with casein resulted in no growth increase. The requirement of the

* The data on metabolizable energy were obtained for the most part from a compilation by F. W. Hill, University of California, Davis, April, 1963, those on productive energy for the most part from the report by Fraps (1946), and the information on feed composition from various sources, including NAS-NRC Pub 659, 1959

chick for molybdenum when fed the casein diet was found to be less than 0.11 p.p.m.

Amounts of molybdenum of 100 p.p.m. or more have been shown by Arthur *et al.* (1958) to cause growth depression in chicks fed a practical diet containing 7.0 p.p.m. The depression was partially overcome at 200 and 350 p.p.m. of molybdenum by addition of copper but not at 500 p.p.m. Davies *et al.* (1957) observed marked growth depression in chicks at 500 p.p.m. of molybdenum which was partially overcome by supplementation with sodium sulfate. These investigators found an anemic condition associated with levels of molybdenum in excess of 2,000 p.p.m. Kratzer (1952) partially overcame growth depression in turkey poults as well as chicks, due to high levels of molybdenum, with added copper.

WATER

The simple chemical compound, water, is of unequalled importance in the metabolism of all animals. Water holds this unique position in nutrition mainly because of its physical properties. Due to its solvent and polar properties, it acts as a transport medium for all other nutrients and products of metabolism and enhances cell reactions. Because of its high specific heat it can absorb the heat of reaction produced in the burning of carbohydrates and fats with little rise in temperature. Water evaporates readily, removing many calories of heat from the body as latent heat of vaporization. These and the many other functions of water make it evident why the animal body is able to exist much longer without food than it can without water.

Importance of a continuous water supply for poultry. Unlike larger farm animals, chickens must have access to a continuous water supply since they drink only a small amount at a time. An insufficient amount of water results in decreased growth and egg production. During severely cold weather it is also necessary to make some provision which will keep the water warm. According to Beresford (1930), failure to warm the drinking water for hens during cold weather results in lowered water consumption and reduced egg production. Hammond (1944) has observed that a lack of water causes the development of loose, slimy gizzard linings which accompany early, nonspecific mortality in turkey poults.

The quantity of water needed by chickens has been found to be related to the amount of some of the nutrients in the diet. Heuser (1952) reported results in confirmation of previous observations which showed that the quantity of water drunk by chicks is correlated directly with the salt content of the diet. Wheeler and James (1950) observed a similar correlation with protein content. Both increased water elimination, the former by increasing the water content of the feces, and the latter by increasing the total fecal excretion. The latter investigators also found that increasing the quantity of soybean meal in the ration increased water intake and elimination.

ENERGY CONTENT AND COMPOSITION OF FEEDSTUFFS

The metabolizable and productive energy content and the amount of protein, fat, fiber, nitrogen-free extract, and mineral matter in the common poultry feedstuffs are given in Table 6.6. In addition, values for calcium and phosphorus content and several of the trace elements are included in the table. Values for vitamin content are given in the chapter on vitamins. With this exception the data in this table, together with the data given in previous ones, provide the basic information needed in the formulation of satisfactory poultry rations.

Vitamins and Vitamin Deficiencies

The term "vitamin" represents a heterogeneous group of fat-soluble and water-soluble chemical compounds, essential in nutrition, which bear no structural or necessary functional relationship to each other. All recognized vitamins, with the exception of vitamin C, are dietary essentials for poultry. Although the amounts of the various vitamins needed in poultry diets range from parts per million down to parts per billion, each of them is required in very exacting amounts for normal metabolism and health. Many of them function as integral parts of vital enzymes. All appear to play various catalytic roles in the many chemical reactions which are concerned in digestion, intermediary metabolism, anabolism, and catabolism within the animal body.

A marked deficiency of a single vitamin in the diet of the chick or turkey poult results in breakdown of the metabolic process in which that particular vitamin is concerned. This causes a vitamin deficiency disease which in some instances exhibits characteristic gross or histopathologic changes. In several instances a disease may occur as a result of a deficiency of any one of several vitamins. Perosis, for example, occurs in young chicks or poults when the diet is deficient in manganese or in any one of the following vitamins: choline, niacin, biotin, or folic acid. Furthermore, the symptoms and pathological changes of several different vitamin deficiencies are very similar in appearance. For example, the gross changes of either pantothenic acid or biotin deficiencies appear as severe dermatoses of the feet and of the areas around the mandibles and the eyes. In this instance, examination of the diet might be necessary to determine the cause of the deficiency.

Ataxia, with characteristic head retractions and convulsive movements, has long been associated with the vitamin E deficiency disease of chicks known as encephalomalacia. Similar symptoms also occur as a result of a severe deficiency of vitamin A in young chicks. In this case histological examination of the brains of chicks suffering from these deficiencies shows that encephalomalacia is caused by a hemorrhagic degeneration in the cerebellum

TABLE 7.1
THE VITAMIN REQUIREMENTS OF POULTRY
(Approximate amounts required per pound of diet)

	Chickens				Turkeys			Ducks
	0–8 wks.	8–18 wks.	Laying hens	Breeding hens	0–8 wks.	8–16 wks.	Breeding turkeys	0–8 wks
Vitamin A, I.U.	1,200	1,200	2,000	2,000	2,400	2,400	2,400	2,400
Vitamin D₃, I.U.	90	90	225	225	400	400	400	100
Vitamin E, I.U.	7	?	?	10	10	8	15	?
Vitamin K, mg.	0.4	0.4	0.4	0 4	0 8	0 8	0.8	0 8
Thiamine (vit. B₁), mg.	0.8	0.8	9 8	1 0	0 9	0 8	1.0	1.0
Riboflavin (vit. B₂), mg.	1.3	0.8	1.0	1.7	1 7	1 5	1.5	1 8
Pantothenic acid, mg.	4.2	4.2	2.1	4 2	5 0	4 5	8 0	5.0
Niacin, mg.	12	10	10	12	35	30	15	25
Pyridoxine (vit. B₆), mg.	1 3	?	1.3	2 0	2 0	1.6	2 0	1.2
Biotin, mg.	0 04	?	?	?	0.06	0.05	0.05	0 05

which is not evident in chicks suffering from the ataxia of vitamin A deficiency.

Usually, after diagnosis of a specific vitamin deficiency, confirmatory evidence can be obtained upon determining, by calculation or analysis, the vitamin content of the ration that was fed to the chicken or turkey and comparing the level found with the known requirement for that particular vitamin.

Therefore, anyone interested in vitamin deficiency diagnosis in poultry must not only be able to recognize the symptoms and lesions of vitamin deficiency diseases, but also must know the vitamin requirements of the various classes of poultry at different stages of development, the vitamin content of the ingredients commonly used in poultry rations, and the metabolic dysfunctions which may result from a deficiency of each of the known vitamins.

Vitamin requirements of poultry. The minimum vitamin requirements of chickens, turkeys, and ducks are presented in Table 7.1. These values were taken in part from the report of the Committee on Animal Nutrition of the National Academy of Sciences — National Research Council (NAS-NRC) on the "Nutrient Requirements for Poultry" (1960).

While all of the vitamins listed in Table 7.1 are needed by poultry, only those require special attention in the formulation of poultry rations which are not present in adequate amounts in the cereal grains and protein supplements used in the rations.

Vitamin A, vitamin D, and riboflavin are the vitamins most apt to be deficient if special attention is not given to provide them when the feed is formulated. Recently, however, due to continued extraction and purification of many common ingredients, and due to the tendency to omit animal proteins and high-fiber ingredients such as alfalfa meal and wheat mill by-products, the amounts of several of the other vitamins have decreased to levels which are sometimes deficient. These are vitamin E, vitamin K, pantothenic acid, vitamin B₁₂, niacin, and choline.

Vitamin content of poultry feed ingredients. The vitamin contents of the common poultry feed ingredients are presented

TABLE 7.2

THE VITAMIN CONTENT OF POULTRY FEEDSTUFFS

Feed	Riboflavin	Niacin	Pantothenic Acid	Choline	Vitamin B₁₂	Vitamin A
	(mg/lb)	(mg/lb)	(mg/lb)	(gm/lb)	(µg/lb)	(I.U./lb)

in Table 7.2. Values are presented for all of the vitamins that are presently considered to be important in the formulation of poultry rations.

From the data in this table it is possible to calculate the vitamin content of most poultry rations when these rations are made up of ingredients of average quality. Poor quality ingredients, of course, cannot be expected to supply the amounts of the vitamins listed in the table.

Present-day poultry rations are usually formulated to contain more than adequate amounts of all of the vitamins listed in Table 7.1 in order to provide margins of safety to compensate for possible losses during feed processing, transportation, storage, and for variations in feed composition and environmental conditions.

If a deficiency should occur, it is usually due either to the inadvertent omission of a critical ingredient during mixing of the feed or to the destruction of one or more of the vitamins during processing of that ingredient. The vitamins which are most prone to suffer destruction are the fat-soluble vitamins, A, D, and E. Under very severe conditions of processing or storage, thiamine and/or pantothenic acid may be destroyed. The special considerations in regard to each vitamin will follow.

VITAMIN A AND VITAMIN A DEFICIENCY

Vitamin A is essential in poultry rations, not only for growth but also for optimum vision and for maintaining the integrity of the mucous membrane. Since this mem-

brane composes the epithelium lining all of those canals and cavities of the body which communicate with the external air, such as the alimentary canal and its branches, the respiratory tract and its connections, and the genito-urinary tract, these are the areas in which lesions of vitamin A deficiency may be detected, either grossly or histologically, depending upon the degree of the deficiency.

Chemical nature of vitamin A. Vitamin A is a fat-soluble, unsaturated, primary alcohol containing one beta ionone ring and a long side chain composed of a series of isoprene units containing conjugated double bonds. The empirical formula is $C_{20}H_{30}OH$. Because of its conjugated system of double bonds, vitamin A is very easily oxidized unless precautions are taken to prevent its destruction. Quackenbush et al. (1942) and others have shown that vitamin E and other natural antioxidants in feeds are essential for the protection of vitamin A. On the other hand, Sumner and Dounce (1939) point out that certain legumes, particularly soybeans, contain an enzyme known as carotene oxidase, which readily destroys the carotenes and xanthophylls, and probably also destroys vitamin A. Proper heat treatment of soybeans, however, should destroy this enzyme.

In view of the difficulty in being assured of adequate vitamin A in poultry and livestock feeds, modern producers of vitamin A supplements have undertaken a great deal of research on methods of stabilizing this vitamin. They have succeeded in greatly enhancing the stability of vitamin A in two ways: (1) by mechanical means, wherein minute droplets of vitamin A are enveloped in a stable fat, gelatin, or wax, forming a small bead which prevents most of the vitamin A from coming into contact with oxygen until it is digested in the intestinal tract of the animal; and (2) through the use of effective antioxidants which markedly prolong the induction period which precedes active oxidation of vitamin A, thereby allowing the vitamin A to be consumed by the

animals before this oxidation takes place. The chief antioxidant in current use is 6-ethoxy-1,2-dihydro-2,2,4-trimethylquinoline (ethoxyquin).

Occurrence. Vitamin A is found only in animal tissue, where it is stored largely in the liver. Although cod liver oil is the most noted source of vitamin A, the livers of shark, tuna, halibut, and many other salt-water species are rich sources of this vitamin. It occurs both as the free alcohol and esterified with various organic acids. Vitamin A, usually as acetate and palmitate esters, is also produced synthetically in this country on a commercial scale. The livers of fresh-water fish contain a biologically active derivative of vitamin A which is known as vitamin A_2. Synthetic and natural vitamin A_2 possess approximately 30 to 40 per cent of the biological activity of vitamin A for poultry.

Pro-vitamins A. Since animals do not have the ability to synthesize vitamin A, all of the natural vitamin A found in body tissues arises originally from precursors of vitamin A which are synthesized by green plants and stored in the green leaves, fruit, and yellow seeds of these plants. These precursors are known as carotenoids. All carotenoids which are precursors of vitamin A contain within their structure at least one complete vitamin A unit with the exception of the alcohol functional group which is attached to the vitamin A moiety by the animal during absorption and degradation of the carotenoid in the intestinal wall of the chick, poult, or other animal. The most abundant precursor of vitamin A in nature is beta-carotene which contains two vitamin A moieties attached to each other. The evidence on the metabolism of beta-carotene indicates, however, that one end of the beta-carotene molecule is destroyed in its conversion to vitamin A, thus allowing only one molecule of vitamin A from each molecule of beta-carotene (Glover and Redfearn, 1954). Beta-carotene is the predominant carotenoid found in green leaves of legumes such as alfalfa

clover and also in green grasses and green vegetables. The other vitamin A precursor of importance in poultry nutrition is cryptoxanthin which is the carotenoid present in yellow corn.

The xanthophylls. In addition to the vitamin A precursors present in green and yellow plants, these materials also contain a number of vitamin A inactive chemical substances closely related to the vitamin A precursors. These substances are known collectively as the xanthophylls. Xanthophylls are absorbed by poultry and are deposited in the eyes, beaks, shanks, adipose tissue, and in the egg yolks. The vitamin A inactive xanthophylls, mainly lutein and zeaxanthin, together with the vitamin A precursor, cryptoxanthin, are largely responsible for the pigmentation of chickens, the color in the iris of the eye, and the yellow color of the yolks. Ganguly *et al.* (1953) showed that beta-carotene is not deposited as such in the chicken or in eggs. Although lutein and zeaxanthin have no vitamin A activity, these xanthophylls may act, to some extent, as antioxidants, and thereby help to preserve vitamin A and its precursors.

Vitamin A requirements of poultry. The vitamin A requirements of poultry of the NAS-NRC (1960) are given in Table 7.1. In arriving at these requirements, the Subcommittee on Poultry Nutrition of the NAS-NRC Committee on Animal Nutrition has considered over 25 reports of research work on the vitamin A requirements of poultry. A review of these reports shows that the vitamin A requirements listed in Table 7.1 were determined with the use of fish liver oils, especially "Reference" cod liver oil, as the sources of vitamin A. In recent research by Hill *et al.* (1961) it was shown that when present-day, commercially stabilized vitamin A preparations are used, the vitamin A requirement of laying and breeding hens approximates 1,200–1,600 I.U. of vitamin A per pound of ration, and the vitamin A requirement of starting chicks is no higher than 600 I.U. per pound of ration. These

results indicate that the true vitamin A requirements of all poultry are considerably less than previously believed, and that the higher apparent requirements are due to oxidative destruction of a large portion of the vitamin A when unstabilized fish oils are used in the course of determining the vitamin A requirements.

Symptoms

Adult chickens. When adult chickens are placed on a diet severely deficient in vitamin A, symptoms develop usually within 2 to 5 months, the length of time depending upon the amount of vitamin A stored in the liver and other tissues of the body. As the vitamin A deficiency progresses, the chickens become emaciated and weak and their feathers are ruffled (Beach, 1924). According to Sherwood and Fraps (1932), there is a marked decrease in egg production, and the length of time between clutches increases greatly. Polk and Sipe (1940) reported that a deficiency of vitamin A causes a great deficiency in hatchability and an increase in embryonic malpositions and mortality in eggs from affected birds. A watery discharge from the nostrils and eyes is noted and the eyelids are often stuck together (Beach, 1924). As the deficiency continues, an accumulation of milky white, caseous material forms in the eyes. In this stage of the disease, the eyes become filled with this white exudate to such an extent that it is impossible for the chicken to see unless the mass is removed; in many cases the eye is destroyed (Beach, 1924; Sherwood, 1939).

Chicks. When day-old chicks are given a vitamin A-deficient diet, the first symptoms may appear at the end of the first week if the chicks were progeny of hens receiving a diet low in vitamin A. On the other hand, if the chicks were progeny of hens receiving adequate amounts of vitamin A, symptoms and lesions of vitamin A deficiency may not appear until the chicks are six or seven weeks of age, even though they are receiving a diet completely

devoid of vitamin A. This is due to the fact that hens receiving adequate amounts of vitamin A store large quantities in their eggs which consequently provide the day-old chick with sufficient reserves to last for an extended period.

Vitamin A deficiency symptoms in chicks are characterized by a cessation of growth, by drowsiness, weakness, incoordination, emaciation, and ruffled plumage. If the deficiency is severe, the chicks show an ataxia not unlike the ataxia of vitamin E deficiency known as encephalomalacia or crazy chick disease (Adamstone, 1947; Hill et al., 1961). A better understanding of the cause of ataxia in vitamin A-deficient chicks may arise from the discovery by Woollam and Millen (1955) that one of the earliest signs of deficiency is an increased pressure of the cerebrospinal fluid. The yellow pigment in the shanks and beaks in breeds of chickens that usually contain this pigment is lost, and the combs and wattles of the chicks are usually pale. In acute vitamin A deficiency, lacrimation may occur and a cheesylike material is seen under the eyelids. Xerophthalmia is a definite symptom of vitamin A deficiency, but all chicks do not exhibit this symptom, because in the acute deficiency they often die of other causes before the eyes become affected.

Turkeys. The vitamin A requirements of turkeys are given in Table 7.1. The length of time required to produce vitamin A deficiency in poults is similar to that required for chicks and depends upon the amount of vitamin A carried over from the hen through the egg to the poult at hatching. Usually vitamin A deficiency symptoms appear in about 4 weeks. If continued on a vitamin A-deficient diet, the turkeys will all die in about 6 weeks (Hinshaw and Lloyd, 1934; Stoewsand and Scott, 1961). Symptoms and lesions of vitamin A deficiency in the turkey are described in Chapter 41.

Vitamin A and bone development. According to Wolbach and Hegsted (1952, 1953), vitamin A deficiency in young ducks

causes marked retardation and suppression of endochondral bone growth, and excess vitamin A produces an acceleration of this bone development. This may be due to alterations in the alkaline phosphatase content of the epiphyseal junction of the bone in ducks similar to that which was shown by Ludwig (1955) for vitamin A deficiency and hypervitaminosis A in rats. The studies reviewed by Wolf and Johnson (1960), however, indicate that effects of vitamin A upon bone development may be secondary to its effects upon mucopolysaccharide biosynthesis in cartilage and connective tissues.

Vitamin A and internal egg quality. Bearse et al. (1953a) reported that the incidence and severity of blood spots in eggs of two different strains of White Leghorn chickens was progressively increased as the level of vitamin A in the diet of the hens was decreased. Recent experiments conducted at Cornell University (Hill et al., 1961) confirm the finding that blood spots are increased in number and severity when hens are fed vitamin A deficient diets. However, these studies showed that the amount of vitamin A required to minimize blood spot incidence is not higher than the vitamin A requirement for good production and health of the laying hens. Certain strains of chickens show a fairly high incidence of blood spots in their eggs which cannot be improved by increasing the vitamin A level in the diet above that needed for satisfactory egg production and health.

Vitamin A, intestinal coccidiosis, and other intestinal parasites. Davies (1952) found that in chickens receiving adequate vitamin A in the form of natural sources of beta-carotene and cryptoxanthin, infecting one group with intestinal coccidiosis caused a reduction in liver stores of vitamin A such that the infected birds had less than 10 per cent as much liver vitamin A as the uninfected controls. These results were confirmed by Erasmus, Scott, and Levine (1960), who showed that although the severity of experimen-

'ly-induced coccidiosis was similar in :'·-ks receiving minimum requirements of vitamin A as compared to chicks receiving higher levels of the vitamin, recovery of surviving chicks, as measured by improved appetites and growth rates, was enhanced as the level of vitamin A in the diet was increased up to a level equivalent to ten times the minimum requirement under normal, nonstress conditions.

Ackert and associates (1931) reported that vitamin A-deficient chicks showed significantly larger numbers and longer intestinal roundworms (*Ascaridia lineata*) than were found in comparable chicks receiving adequate vitamin A. This work has been criticized on the basis that it is very difficult to determine total numbers of roundworms in the intestinal tract of chickens and that the number may vary considerably from day to day.

Pathology

Adult chickens. According to Seifried (1930a), when adult chickens are placed on a diet lacking vitamin A, lesions first appear in the upper alimentary tract and are largely confined to the mucous glands and their ducts. The original epithelium becomes replaced by a stratified squamous,

keratinizing epithelium which blocks the ducts of the mucous glands causing them to become distended with secretions and necrotic materials. Small, white pustules are found in the nasal passages, mouth, esophagus, pharynx, and may extend into the crop. The pustules may range in size from microscopic lesions to 2 mm. in diameter (Fig. 7.1). As the vitamin A deficiency progresses, the lesions become larger and are raised above the surface of the mucous membrane and show a depression in the center. Small ulcers surrounded by inflammatory products may appear at the site of these lesions. This condition closely resembles certain stages of fowl pox, and the two conditions can be differentiated only by microscopic examination. Due to the breakdown of the original mucous membrane, bacteria, viruses, and other pathogenic microorganisms may invade these tissues and enter the body, thereby producing infections which are secondary to the original vitamin A deficiency symptoms.

Chicks. Young chicks suffering from chronic vitamin A deficiency show lesions in the mucous membranes of the head, esophagus, crop, and respiratory tract. The kidneys become pale and show a network
FIG. 7.1 – Pustulelike lesions in pharynx and esophagus — vitamin A deficiency. (Biester and Schwarte, No. Am. Vet.)

of fine white lines. These are the renal tubules filled with white urates. In extreme cases, even the ureters are filled with urates. According to Elvehjem and Neu (1932), the blood level of uric acid increases from a normal of about 5 mg. to as high as 44 mg. per 100 cc. of whole blood during severe vitamin A deficiency. Deposits of urates have been found on the heart, pericardium, liver, and spleen of affected birds. Elvehjem and Neu found that vitamin A deficiency does not disturb uric acid metabolism, but injures the kidney in such a way as to prevent normal excretion of uric acid.

The clinical symptoms and pathological lesions of vitamin A deficiency of the respiratory tract are variable, and it is difficult to differentiate this condition from infectious coryza, virus diphtheria, and infectious tracheal bronchitis (Beach, 1924; Seifried, 1930b). In vitamin A deficiency, thin membranes and nasal plugs appear but are usually limited to the cleft palate and its adjacent epithelium. They may be removed easily without bleeding. According to Seifried, this is not true in virus diphtheria. Atrophy and degeneration of the respiratory mucous membrane and its glands occur. Later the original epithelium is replaced by a stratified squamous, keratinizing epithelium. In the early stages of vitamin A deficiency in chickens, the turbinates are filled with seromucoid waterclear masses, which may be forced out of the nodules and cleft palate by the application of slight pressure. In the early stage of the disease, the vestibule becomes plugged and overflows into the paranasal sinuses. The exudate may also be forced through the cleft palate producing a white, or slightly yellow, caseous mass which fills the sinuses and other nasal cavities. This causes a swelling of one or both sides of the face. After the sinuses have filled, the tear ducts become occluded. The eyeball is pressed against the frontal bones and is sometimes forced out to the side because it cannot move in a ventral direction. Upon removal of the inflammatory products, the mucous membranes of the nasal passages, sinuses, mouth, and throat appear thin, rough, and dry. Unattached masses of caseous material often form in the cleft palate and in the mucous membranes of the roof of the mouth.

Lesions in the larynx and trachea of vitamin A-deficient chickens occur both in the early and in the later stages of the disease. Near the entrance of the pharynx, the lesions consist of pustulelike patches of white, caseous material. Caseous and crumbly white masses often appear in the mucous membrane on the ventral side of the anterior end of the larynx, and in the pointed angle which is formed by the cartilage of the larynx. Frequently, similar lesions may be found in the trachea and bronchi. In the early stages these may be difficult to see. As the condition progresses, the mucous membrane is covered with a dry, dull, and fine film, which is slightly uneven, whereas the normal membrane is even and moist. In some cases, small, nodulelike particles are in or beneath the mucous membrane in the upper part of the trachea. These lesions are much more striking in the latter stages of the deficiency and may then be seen easily with the naked eye. The formation of a thin membranous covering over the mucosa of the trachea and bronchi is a symptom of vitamin A deficiency, but is often mistaken for the symptom of infectious tracheitis (Fig. 7.2). The smaller bronchi often become completely occluded by these membranes. As a result, in some cases the most marked changes appear in the larynx, while in others these appear in the trachea.

Histopathology

The first histologic lesion of vitamin A deficiency is an atrophy of the cytoplasm and a loss of the cilia in the columnar ciliated epithelium (Seifried, 1930a). The nuclei often present marked karyorrhexis. A pseudomembrane, formed by the atrophying and degenerating ciliated cells, may hang as tufts on the basement membrane; later these are sloughed. During this process, new cylindrical or polygonal cells may be formed either singularly or in

FIG. 7.2 — Trachea of chicken with A avitaminosis showing desquamated epithelium partly in the form of a tube. Bird died after 87 days on experimental diet. (Seifried, Jour. Exper. Med.)

pairs, and appear as islands beneath the epithelium. These new cells become more and more numerous, and their nuclei become larger and contain less chromatin as they develop. The cell boundaries become less clearly defined; finally, the columnar ciliated epithelial lining of the trachea, bronchi, and submucous glands becomes transformed into a squamous, stratified, keratinizing epithelium (Fig. 7.3). Seifried (1930b) concluded that this process is not related to bacterial infection.

The nasal cavities and communicating sinuses show essentially the same epithelial lesions as the trachea. All parts of the nasal cavities are usually involved. There is an increased proliferation of the superficial epithelial cells in the gland-free part of the nasal vestibule. A true keratinization, similar to that found in the trachea, appears in

the mucous membrane of the roof of the nasal vestibule. Seifried (1930b) found that the epithelium of the submucous glands becomes involved somewhat later than the epithelium of the mucous membrane. Keratinization occurs in the excretory duct of the lateral nasal gland and in the nasolacrimal duct.

Jungherr (1943) stated that histopathological examination of tissues from the nasal passages of chicks serves as the most sensitive indicator of borderline deficiencies of vitamin A. Chicks receiving borderline deficient levels of vitamin A show lesions which resemble, in basic character, but not in severity, those described by Seifried (1930b) for a complete deficiency of vitamin A. The specific lesion in both cases consists of squamous metaplasia of the secretory and glandular

FIG. 7.3 — Cross section through trachea showing newly formed stratified epithelium. Several cells near surface showing "balloon" degeneration. ×990. (Seifried, Jour. Exper. Med.)

FIG. 7.4 — Cross section through base of tongue showing early keratinization and degeneration of the upper layers of the newly formed epithelium. X80. (Seifried, Jour. Exper. Med.)

epithelium with inflammatory or obstructive changes secondary in nature. The metaplastic changes are first noted, microscopically, near the mucocutaneous junction in the septum or the medial convexity of the anterior turbinate.

Further evidence that vitamin A is directly concerned with the differentiation of the mucous membrane was obtained by Fell and Mellanby (1953), who showed that explants of chick ectoderm, when grown in a tissue culture supplemented with a high level of vitamin A, failed to develop into typical keratinized epithelium Instead, the cells differentiated into mucus-secreting, often ciliated columnar epithelial cells, resembling those of the nasal mucosa. Kahn (1954) extended these findings by showing that added vitamin A prevents keratinization that otherwise occurs in explants of rat vaginal epithelium.

Lesions in the glands of the tongue, palate, and esophagus are very much the same as those found in the respiratory tract (Seifried, 1930a). The early lesions occur in the collecting spaces and ducts and may appear first in the maxillary and submaxillary glands (Fig. 7.4). As the disease progresses, the collecting spaces become filled with masses of mucus, degenerated cells, and inflammatory products. The epithelium extends into the ducts, which become partially filled with the stratified, keratinized epithelium, and more or less complete occlusion results (Fig. 7.5). Desquamated cells from the newly formed stratified epithelium become more and more numerous. The glands become smooth and distended, although originally they were sacs with invaginations. These distended sacs finally become completely filled with stratified keratinized epithelial cells. Seifried believes that these lesions are responsible for the fact that bacterial infections are more prevalent in the mouth cavity than in the crop and esophagus during avitaminosis A.

Adamstone (1947) conducted investigations to differentiate, by histologic

citric acid metabolism, since Steenbock and Bellin (1953) and Bellin et al. (1954) showed that vitamin D increases the urinary excretion of citrate and the citrate content of bone, kidney, heart, and small intestine, but not of the livers of rats fed normal or rachitogenic diets. Steenbock and Herting (1955) concluded that vitamin D is required for growth and for normal functioning of citric acid metabolism, independently of its effects upon bone calcification.

Chemical nature and occurrence. Vitamin D is the general term applied to a number of fat-soluble sterol derivatives which are active in the prevention of rickets in animals. Although there are numerous chemically distinct forms of vitamin D, when measured by their capacity to prevent or cure rickets in rats or other mammals, only one form, activated 7-dehydro-cholesterol (vitamin D_3), has been found to have an appreciable effect in the prevention of rickets in poultry.

Vitamin D_3 is produced by irradiation of 7-dehydro-cholesterol with ultraviolet light, either from the sun or from an artificial source. It is synthesized by animals and is found in the skin, butter fat, egg yolk, fish oils, and other lipids throughout the animal body or its products. According to Koch and Koch (1941), the skin of the legs and feet of poultry contains about eight times as much provitamin D_3 as the body skin. Spectrophotometric examination of ether extracts from leg skin showed the presence of 7-dehydro-cholesterol in relatively high amounts. In contradiction of the claims of Hou (1928, 1931) the preen gland contained very little, if any, provitamin D_3. Upon being produced on the skin surface by irradiation, vitamin D_3 is absorbed through the skin and transported to the liver by the blood and stored there for future use. Thus tuna, halibut, and other liver oils are rich in vitamin D_3. However, in poultry rations the chief source of vitamin D_3 arises from the commercial separation and irradiation of animal sterols known as "D-activated animal sterols." From these, feed supplements of guaranteed potencies are prepared.

Vitamin D_2, which is effective for most mammals, is not a satisfactory antirachitic vitamin for poultry. Vitamin D_2 is produced by the irradiation of the plant sterol, ergosterol. Bethke et al. (1936) found that vitamin D from cod liver oil was approximately 10 times as active, on a rat unit basis, as irradiated ergosterol for egg production in hens maintained in strict confinement. Dihydrotachysterol has been shown by McChesney (1943), Fritz et al. (1945), and Motrok et al. (1946) to possess antirachitic activity for chicks. However, the activity of this compound is somewhat less than that of vitamin D_3. Cod liver oil and other fish liver oils appear to contain mixtures of antirachitic sterols. Therefore, these oils usually are not as active for poultry as vitamin D_3 (Singsen and Mitchell, 1945) when measured in equivalent doses of rat-active vitamin D. Boucher (1944) showed that in turkey poults, irradiated animal sterols and irradiated 7-dehydro-cholesterol were approximately twice as active as the vitamin D from reference cod liver oil or fortified sardine oil when fed on the basis of their A.O.A.C. unit potencies.

The International Unit of vitamin D is represented by an antirachitic activity for chicks equivalent to that of 0.025 microgram of crystalline vitamin D_3. In converting the older A.O.A.C. unit of vitamin D activity for chicks to International Units, the A.O.A.C. units must be reduced 25 per cent.

Vitamin D_3, like vitamins A and E, is unstable. Although Baird et al. (1939) detected no vitamin D destruction in a mixed feed stored at summer temperatures for 32 weeks, Norris et al. (1929) reported that the addition of cod liver oil to finely divided feed mixtures at the minimum protective dosage resulted in a material destruction of vitamin D, when the feed was stored at room temperature from 12 to 16 weeks preceding consumption.

a D-activated animal sterol supplement was premixed with aCl and $CaCO_3$ and stored for 3 weeks, of the vitamin D was destroyed (Milby and Thompson, 1943). Fritz et al. (1942) showed that vitamin D premixed with oystershell flour, dried whey, dried skim milk or mineral mixtures also lost most of its activity within one month. Miller et al. (1942) found that although 0.5 per cent $MnSO_4$ added to a premix of 9 per cent cod liver oil on bran caused destruction of both vitamin A and vitamin D, there was no destruction in a finished feed with or without the addition of 4 oz. of $MnSO_4$ per ton of feed. Although most mixed feeds apparently contain sufficient vitamin E and other natural antioxidants to prevent destruction of vitamin D, it now appears practicable to use small amounts of the synthetic antioxidant, ethoxyquin, to further protect the vitamin D potency of poultry feeds.

Vitamin D requirements of poultry. The vitamin D_3 requirements of poultry depend upon the sources of phosphorus in the ration, the amounts of and the ratio of calcium to phosphorus, and the extent of exposure to direct sunlight. Hart et al. (1923), Mussehl and Bancroft (1925), and Heuser and Norris (1929) showed that 11 to 45 minutes of sunshine, daily, was sufficient to prevent rickets in growing chicks, and that no further improvements in growth were obtained under these conditions by adding cod liver oil.

The vitamin D requirements of poultry, presented in Table 7.1, are sufficiently high to produce normal growth, calcification, production, and reproduction in the absence of sunlight, provided that the diets contain the recommended levels of calcium and available phosphorus. The requirements of turkeys for vitamin D are considerably higher than the requirements of chickens, although studies on the vitamin D requirements of turkeys have yielded conflicting results. Some studies have indicated turkey requirements to be even higher than those given in Table 7.1.

Further research is needed to determine the reason for the very high vitamin D requirements of turkeys as compared to chickens.

Symptoms

Mature chickens. According to Hughes and Payne (1924) and Doyle (1925), symptoms of vitamin D deficiency begin to occur in laying hens in confinement about 2 to 3 months after they are deprived of vitamin D. The first symptom is a marked increase in the numbers of thin-shelled and soft-shelled eggs, followed soon afterward by a marked decrease in egg production. Hatchability is also markedly reduced. This is due, according to Hart et al. (1925a), to a lack of calcium in the embryos from vitamin D-deficient hens.

Individual hens may show temporary loss of use of the legs, with recovery after laying an egg, usually a shell-less egg. During the periods of extreme leg weakness, the hens show a characteristic posture which has been described as a "penguin-type squat." Later, the beak, claws, and keel become very soft and pliable. The sternum usually is bent and the ribs lose their normal rigidity and turn inward at the junction of the sternal and vertebral portions. This produces a characteristic inward curve of the ribs along the sides of the thorax.

Chicks. In addition to retarded growth, the first symptom of vitamin D deficiency in chicks is rickets, which is characterized by a severe weakness of the legs. The beaks and claws become soft and pliable. This usually appears between 2 and 3 weeks of age. The chicks walk with obvious effort and take only a few unsteady steps before squatting on their hocks, whereupon they rest, but at the same time sway slightly from side to side, indicating a lack of complete sense of equilibrium. The feathering is poor and in New Hampshire (Glazener et al., 1946) and Buff Orpington × Rhode Island Red (Lillie and Bird, 1919) chicks, an abnormal blackening of the feathers is observed in vitamin D deficiency. Buff

Plymouth Rock chicks fed vitamin D-deficient rations, however, showed all of the symptoms of rickets, but did not show blackening of the feathers.

In chronic vitamin D deficiency, marked skeletal distortions become apparent. The spinal column may bend downward in the sacral and coccygeal region. The sternum usually shows both a lateral bend and an acute dent near the middle of the breast. These changes reduce the size of the thorax, with consequent crowding of the vital organs.

Turkeys. Vitamin D deficiency in turkeys is described in Chapter 41.

Pathology

Mature chickens. In hens receiving a deficient amount of vitamin D, the characteristic changes observed on postmortem are confined to the bones and parathyroid glands. The bones are soft and break easily. Well-defined knobs are present on the inner surface of the ribs where the sternal portions join the vertebral portions. Many of the ribs show evidence of spontaneous fracture in this region. Skeletal changes also appear in the vertebral column, pelvis, and sternum. Histological sections of the leg bones show a deficiency of calcium and an excess of osteoid tissue.

Chicks. The most characteristic internal signs of vitamin D deficiency in chicks are a beading of the ribs at their juncture with the spinal column and a bending of the ribs downward and posteriorly (Fig. 7.6).

Poor calcification can be observed at the epiphysis of the tibia or femur. By dipping the split bone in silver nitrate solution and allowing it to stand under an incandescent light for a few minutes, the calcified areas are easily distinguished from the areas of uncalcified cartilage (Fig. 7.7).

Hypervitaminosis D. Very high levels of vitamin D, 2,000,000 I.U. or more per pound of diet, cause renal damage. This is due to calcification of the kidney tubules, and usually calcification in the aorta and other arteries, especially the blood vessels of the spleen (Seifried and Heidegger,

FIG. 7.6 — Rickets in the chicken, showing severe beading and curvature of the ribs and spinal column.

1933; van Niekerk and Franken, 1937). Irradiated ergosterol (vitamin D_2) at high levels also is toxic to chickens (Hall and King, 1931; Bethke et al., 1936).

Frölich (1954) reported that vitamin D_3, at levels of 290 and 640 I.U. per pound of diet, inhibited growth in vitamin B_{12} deficient chicks. Addition of adequate vitamin B_{12} to the diet caused maximum growth at both levels of vitamin D, which was superior to that obtained with 90 I.U. of vitamin D_3 per pound of diet in the presence of adequate vitamin B_{12}.

Vitamin D and hormones. Vitamin D_3, at a level in the diet which was 10 times that required for prevention of rickets, caused increases in the linear measurements and weights of the combs, wattles, and gonads in New Hampshire cockerels at 14 and 18 weeks of age as compared to the measurements and weights of these tissues in cockerels of equal body weight receiving the minimum antirachitic dosage of vitamin D_3 (Buckner et al., 1951).

Landauer (1954) found that estrogen treatment of vitamin D-deficient cockerels
FIG. 7.7 — Tibia of a severely vitamin D-deficient, rachitic chick (445) and a normal chick (235), after staining with silver nitrate and exposure to light.

with daily intramuscular injections of 2 mg. of estradiol benzoate prevented loss of muscular control and reduced the severity of rickets, but had no effect upon the enlargement of the parathyroid glands during a 57-day experimental period.

McGinnis et al. (1947) found that the abnormal feather pigmentation in vitamin D-deficient New Hampshire chicks could be altered by thyro-active compounds and diethylstilbestrol. Iodinated casein tended to increase the amount of black pigment, while thiouracil or diethylstilbestrol decreased the deposition of black pigment. Thyroid hormone has been shown by Gutteridge and Novikoff (1947) also to be interrelated with vitamin D in the improvement of eggshell strength.

Treatment of vitamin D deficiency. Hooper et al. (1942) found that the feeding of a single massive dose of 15,000 I.U. of vitamin D_3 cured rachitic chicks more promptly than when generous levels of the vitamin were added to the feed. This single oral dose protected cockerels against rickets for a period of 8 weeks, and pullet chicks for 5 weeks. In giving massive doses to rachitic chicks, it should be remembered that excess vitamin D can be harmful. The dose should be scaled to the degree of the deficiency and the amount of vitamin D added to the feed should not be excessive.

VITAMIN E AND VITAMIN E DEFICIENCY

Vitamin E deficiency produces encephalomalacia, exudative diathesis, and muscular dystrophy in chicks, enlarged hocks, and dystrophy of the gizzard musculature in turkeys, and muscular dystrophy in ducks. It is also required for normal embryonic development in chickens, turkeys, and probably ducks. Prolonged vitamin E deficiency produces testicular degeneration and lack of fertility in male chickens.

Although the metabolic action of vitamin E is not known, Goldstein and Scott (1956) showed that the albumin level is markedly reduced in the plasma of vitamin E-deficient chicks. Creatine excretion is increased and muscle creatine levels are decreased in vitamin E-deficient chicks and poults.

In its alcoholic form, vitamin E is a very effective antioxidant. In this capacity, it is an important protector in feeds of the essential fatty acids and other highly unsaturated fatty acids as well as vitamin A, vitamin D_3, the carotenes, and xanthophylls. Recently selenium, at levels of 0.01

to 0.1 p.p.m., has been shown to prevent or cure exudative diathesis in vitamin E-deficient chicks (Scott *et al.*, 1957; Schwarz *et al.*, 1957; Patterson *et al.*, 1957). Work by Scott (1962a, 1962b) shows that vitamin E plays a multiple role in the nutrition of poultry. It is required not only for normal reproduction but also (1) as nature's most effective antioxidant for prevention of encephalomalacia, (2) in a specific role, interrelated with the action of selenium, for prevention of exudative diathesis, and (3) in another role, interrelated with both selenium and cystine, for prevention of nutritional muscular dystrophy. A review of the work on selenium is contained in the previous chapter.

Chemical nature and occurrence of vitamin E. Vitamin E is the name applied to a group of fat-soluble, unstable organic compounds known as the tocopherols. d-Alpha-tocopherol possesses the greatest degree of vitamin E activity.

The tocopherols are found in the germ oils of seeds such as wheat, corn, and soybeans, and in alfalfa meal. Commercial vitamin E supplements are produced by molecular distillation of the alpha-tocopherol from vegetable oils or by chemical synthesis of *dl*-alpha-tocopherol.

Since esterification of the vitamin improves its stability, the commercial supplements usually contain *d*-alpha-tocopheryl acetate or *dl*-alpha-tocopheryl acetate. One International Unit of vitamin E is equivalent to the activity of one mg. of *dl*-alpha-tocopheryl acetate. Because the *l*-isomer is less active, *d*-alpha-tocopheryl acetate possesses an activity of 1.36 I.U. per mg. Unesterified *dl*-alpha tocopherol has a potency of 1.1 I.U., while that of *d*-alpha-tocopherol is 1.49 I.U. per mg.

Vitamin E is very unstable. Its oxidative destruction is enhanced by minerals and by unsaturated fatty acids in the diet. When a diet contains fish liver oils in any quantity, an effective antioxidant also should be added in order to prevent the oils from undergoing oxidative rancidity.

Following the initial discovery by Sing-

sen *et al.* (1953) that the antioxidant diphenyl-*p*-phenylenediamine has a marked sparing effect upon vitamin E, a number of other antioxidants have been developed which also help preserve vitamins E, A, and xanthophylls in poultry feeds. Among these, the most widely used is 6-ethoxy-1,2-dihydro-2,2,4-trimethylquinoline (ethoxyquin).

Vitamin E requirements of poultry. Although both selenium, in small amounts, and antioxidants are helpful in sparing the requirements for vitamin E for certain functions, it is still necessary to be certain that practical poultry rations contain sufficient amounts of vitamin E *per se*. The approximate requirements of chickens and turkeys are presented in Table 7.1.

Symptoms and Pathology

Mature chickens. No outward symptoms occur in mature chickens receiving very low levels of vitamin E over prolonged periods. Hatchability, however, is reduced markedly (Adamstone, 1931; Adamstone and Card, 1934). Embryos from hens fed vitamin E-low rations may die as early as the fourth day of incubation. Testicular degeneration occurs in males deprived of vitamin E over prolonged periods of time.

Encephalomalacia in chicks. Encephalomalacia is a nervous derangement characterized by ataxia, backward or downward retractions of the head, sometimes with lateral twisting, forced movements, increasing incoordination, a rapid contraction and relaxation of the legs, and finally complete prostration and death (Fig. 7.8). Even under these conditions, complete paralysis of the wings or legs is not observed. The deficiency usually manifests itself between the fifteenth and the thirtieth day of the chick's life, although it has been known to occur as early as the seventh day and as late as the fifty-sixth day.

Pappenheimer and Goettsch (1931) and Pappenheimer *et al.* (1939) reported that the cerebellum, the cerebral hemispheres, the medulla, and the midbrain are

FIG. 7.8 — Encephalomalacia.

affected most commonly in the order named. In chicks which are killed soon after the appearance of symptoms of encephalomalacia, the cerebellum is softened, swollen, and the meninges are edematous. Minute hemorrhages are often visible on the surface of the cerebellum. The convolutions are flattened. In some cases, as much as four-fifths of the cerebellum may be affected, while in others lesions may be so small that they cannot be recognized grossly. A day or two after the symptoms of encephalomalacia are first manifested, the necrotic areas present a greenish-yellow opaque appearance. Healing sometimes occurs spontaneously, in which case the affected areas are shrunken and depressed below the surface of the healthy tissue, and the color changes to brownish-yellow.

In the cerebrum, the necrotic tissue is frequently pale, swollen, and wet, and in the early stages becomes sharply delineated from the remaining normal tissue (Pappenheimer et al., 1939). Some cases are so affected that the greater portion of both hemispheres in the cerebrum are destroyed. Other cases are so mildly affected that lesions are apparent only on microscopic examination. In the cerebrum also the affected tissue is greenish-yellow, but when healing has occurred, the color changes to a rusty brown.

Medullary lesions are not so readily noted in a macroscopic examination (Pappenheimer et al., 1939). A flattening and general swelling of the ventral surface indicates the presence of internal lesions. After one is familiar with the disease, a macroscopic diagnosis can be made correctly in approximately 90 per cent of the cases.

The microscopic lesions of the cerebellum are characteristic, but are variable in extent and distribution (Wolf and Pappenheimer, 1931; Pappenheimer et al., 1939; and Scott and Stoewsand, 1961). In all cases, edema in the beginning is followed by capillary hemorrhages, thrombosis, and necrosis of neuroglial elements and ganglion cells. Edema is probably the most constant and striking feature; it results in structural changes in the convolutions and obliteration of the sulci. Edema is apparent in the Purkinje cell zone and results in a cribriform structure. The Purkinje cells, Golgi cells, and small cells of the granular layer undergo a degeneration known as ischemic necrosis (Fig. 7.9). The Purkinje cells become angular and narrow and lose their Nissl substances; their nuclei become pyknotic. Nuclei of the Bergmann cells are swollen.

One of the earliest recognizable lesions of encephalomalacia is a circulatory disturbance in the brain (Wolf and Pappenheimer, 1931; Pappenheimer et al., 1939). The pial vessels and the capillaries of the granular and molecular layers, and the cap-

FIG. 7.9 — Encephalomalacia in the chicken. (Above) normal brain shows well-defined row of Purkinje cells between granular and molecular layers of cerebellum. ×300. (Below) Brain of chicken with encephalomalacia shows pyknosis and destruction of Purkinje cells and separation of granular and molecular layers of cerebellum. ×600. (Scott and Stoewsand, 1961)
ries of the central white matter in the ·' of the cerebellum are engorged with ,throcytes. Not all vessels are distended · manner; some vessels are distended thile others are collapsed. This is particu- '; true in the white matter, but less often the granular layers, and is only occasion- lly noted in the lower portion of the mo- 'ecular layer. Large numbers of small nemorrhages are found in the pia and cere- bellar layers and are very conspicuous in the lower portion of the molecular layer. The fibers of the white matter are sepa- rated by a mild edema. Hyaline capillary thrombi appear even in the most recent and small areas of necrosis and are a very constant feature of the lesions. When the capillaries undergo repair, the endothelial cells become greatly swollen and grow very actively; they quite often sprout laterally into the necrotic tissues. The lesions in the cerebrum, midbrain, and medulla are very much like those of the cerebellum. Cere- bral lesions appear to result from vascular disturbances, but the vascular disturbances are not associated with significant alter- ations in cell plasma ratio, plasma, or blood volume (Pappenheimer and Graff, 1932; and Pappenheimer et al., 1939).

Exudative diathesis in chicks. Exudative diathesis is an edema of the subcutaneous tissues associated with abnormal perme- ability of the capillary walls (Dam and Glavind, 1939). In severe cases, the chicks stand with their legs far apart as a result of the accumulation of the fluid under the ventral skin. This greenish-blue, viscous fluid is easily seen through the skin, since it usually contains some blood components arising from slight hemorrhages which appear throughout the breast and leg mus- culature and in the intestinal walls. Dis- tension of the pericardium and sudden deaths have been noted. The onset of the condition coincides with the appearance of peroxides in the tissues.

Chicks suffering from exudative diathesis show a fairly severe microcytic anemia (Scott et al., 1955), a low ratio of albumin to globulins (Goldstein and Scott, 1956), and a low muscle creatine.

Muscular dystrophy in chickens, duck- lings, and turkeys. When vitamin E de- ficiency is accompanied by a sulfur amino acid deficiency, chicks show symptoms of muscular dystrophy, particularly of the breast muscle, at about 4 weeks of age. The condition is characterized by light colored streaks of easily distinguished affected bundles of muscle fibers in the breast (Fig. 7.10). A similar dystrophy occurs in vita- min E deficient ducks where it is general throughout all skeletal muscles of the body. Upon histological examination, and the intramuscular tissue is edematous, and the muscle fibers are seen to have undergone hyaline degeneration, leaving only masses of cell nuclei apparent in some areas. Vita- min E and selenium deficiency in chickens and, especially, in turkeys, may result in an extreme dystrophy of the gizzard muscle (Salisbury et al., 1962; Walter and Jensen 1963). According to Walter and Jensen (1963) this gizzard dystrophy in turkeys is prevented by supplementing deficient diets with either vitamin E or selenium. It is not affected by the dietary level of sulfur amino acids.

Enlarged hock disorder in turkeys. Turkeys receiving low vitamin E diets, con- taining 2 per cent level of cod liver oil, develop characteristic hock en- largements and bowed legs at approxi- mately 2 to 3 weeks of age (Scott, 1951). As the poults are allowed to continue to grow on these diets, the hock enlargements usually disappear by the time the poults are 6 weeks of age, only to reappear in more severe form when the turkeys reach 14 to 16 weeks of age, especially in toms raised on wire or slat floors. Creatine ex- cretion is increased and muscle creatine levels are reduced.

The development of enlarged hocks ap- pears to be a weakness in turkeys which may result from a number of deficiencies and stresses. In addition to the need for adequate vitamin E, it appears that phos- phorus, choline, glycine, niacin, zinc, and unknown factors are needed in adequate amounts for the prevention of the enlarged

FIG. 7.10 — Nutritional muscular dystrophy in the chicken. White striations are degenerated muscle fibers clearly visible in the muscles of the breast and leg.

hock disorder (Slinger *et al.*, 1954; Scott, 1950; Scott, 1953). Two infectious diseases, synovitis and staphylococcic arthritis, may show somewhat similar symptoms.

Treatment of vitamin E deficiency. Symptoms of exudative diathesis and muscular dystrophy in chicks are readily reversed, if not too far advanced, by administration of vitamin E, either by oral dosing or in the feeds. Oral administration of a single dose of 300 I.U. of vitamin E per chick caused remission of exudative diathesis and maintained the chicks in normal condition for about one week after dosing (Goldstein and Scott, 1956). Encephalomalacia may or may not respond to treatment with vitamin E, depending upon the extent of the damage to the cerebellum.

VITAMIN K AND VITAMIN K DEFICIENCY

Vitamin K is required for the synthesis of prothrombin within the body. Since prothrombin is an important part of the blood-clotting mechanism, a deficiency of vitamin K results in a markedly prolonged blood-clotting time, such that an affected chick or poult may bleed to death from a slight bruise or other injury.

Chemical nature and occurrence. Two forms of vitamin K, vitamin K_1 and vitamin K_2, exist in nature. Each has a 2-methyl-1,4-naphthoquinone nucleus with a side chain. Vitamin K_1 has a phytyl side chain made up of four isoprene units with the empirical formula of $C_{20}H_{31}OH$; vitamin K_2 has a difarnesyl side chain of six isoprene units, with the empirical formula of $C_{30}H_{49}OH$. Many synthetic 2-methyl-1,4-naphthoquinones have variable amounts of vitamin K activity, depending upon the makeup of the side chain. Synthetic vitamin K (K_3 or menadione), however, has a single hydrogen atom in place of the side chain.

The richest sources of vitamin K (K_1) are the green leaves of plants such as

a and green grasses. However, soybean oil also contains this vitamin. Vitamin K_2 is synthesized by a number of bacteria, and, therefore, is present in materials which have promoted the growth of these bacteria. This form of the vitamin has been isolated from fish which has been subjected to bacterial action. However, because of improved processing, present-day fish meal may not represent a dependable source of the vitamin. Although vitamin K_2 is synthesized in the intestinal tracts of chickens and turkeys, it appears too far down the tract to furnish these species with all of their vitamin K needs.

Requirements. The vitamin K_1 requirement of young chicks is presented in Table 7.1. This requirement is based upon practical diets in the absence of stress agents, such as sulfaquinoxaline, which may increase the requirement. When sulfaquinoxaline or other drugs are present in the feed or in the drinking water, supplementary menadione sodium bisulfite is usually added at levels of 2 to 3 gm. per ton of feed.

Symptoms and Pathology

Symptoms of vitamin K deficiency occur most frequently about 2 to 3 weeks after chicks are placed on a vitamin K-deficient diet. The presence of sulfaquinoxaline in the feed or in the drinking water may increase the incidence and severity of the symptoms. Large hemorrhages appear on the breast, legs, wings, and/or in the abdominal cavity. The chicks show an anemia which may be in part due to the loss of blood but also due to the development of a hypoplastic bone marrow. Although blood-clotting time is a fairly good measure of vitamin K deficiency, a more accurate measure is obtained by determining the "prothrombin-time."

Treatment. Within 4 to 6 hours after vitamin K is administered to deficient chicks, the blood clots normally, but recovery from the anemia or disappearance of the hemorrhages cannot be expected to take place promptly. Failure to realize this may account for the apparent failure of recovery from some cases of "field hemorrhagic syndrome" upon treatment with menadione sodium bisulfite.

THIAMINE (VITAMIN B_1) AND THIAMINE DEFICIENCY

Thiamine is required by poultry for the metabolism of carbohydrates. In the body, it becomes an important part of the enzyme, carboxylase, which is concerned in a number of reactions involving pyruvate, one of the end products of carbohydrate catabolism. Deficiency of thiamine in poultry leads to extreme loss of appetite, polyneuritis, and death.

Chemical nature and occurrence. Thiamine is a water-soluble, heat-unstable compound consisting of a thiazole ring attached to a pyrimidine nucleus by a methylene linkage. The thiazole moiety contains a two carbon side chain with a terminal primary alcohol grouping, which is the site of attachment of phosphoric acid in the formation of cocarboxylase.

The cereal grains and their by-products, soybean meal, cottonseed meal, peanut meal, and alfalfa meal are all relatively rich sources of thiamine. Thus, under normal circumstances, all practical poultry rations contain adequate thiamine without the addition of special feed supplements high in thiamine.

Under certain conditions, however, a thiamine deficiency in a poultry feed may be created. Thiamine is very unstable to be created. Thiamine is very unstable to heat under neutral and alkaline conditions. Tests show that while no destruction occurs in 1 per cent HCl during 7 hours at 100° C., 96.4 per cent destruction occurs under the same conditions at pH 7, and 100 per cent destruction occurs in 15 minutes at pH 9 at 100° C. Poultry rations, therefore, especially pelleted rations, should not contain alkaline salts in sufficient quantities to produce an alkaline reaction in the feed. Bisulfite ions are also very destructive of thiamine, cleaving the molecule into the pyrimidine and thiazole

parts. An enzyme called thiaminase, capable of destroying thiamine, exists in fresh fish (Green et al., 1912) and in other materials, including the heart and spleen of warm-blooded animals (Somogyi, 1952). Oxythiamine is a potent antagonist of thiamine (Daniel and Norris, 1949). When this compound is present in the diet, much more thiamine is required to prevent a deficiency. According to Bhagvat and Devi (1944), many natural feedstuffs, such as beans and mustard seed, contain antithiamine-active compounds.

Requirements. The thiamine requirement of young chicks is shown in Table 7.1. This requirement is easily met by most practical feeds.

The thiamine requirements of breeding hens and of starting and breeding turkeys also are easily met by practical feedstuffs without special supplementation.

Symptoms and Pathology

Thiamine deficiency or polyneuritis, as it is usually called, is observed in mature chickens approximately 3 weeks after they are placed on a thiamine-deficient diet. In young chicks, it may appear before 2 weeks of age. The onset of symptoms is sudden in young chicks and more gradual in mature birds. Anorexia is the first symptom, followed by loss in weight, ruffled feathers, leg weakness, and an unsteady gait. Adult chickens often show a blue comb. As the deficiency progresses, apparent paralysis of the muscles occurs, beginning with the flexors of the toes and progressing upward, affecting the extensor muscles of the legs, wings, and neck. The chicken, characteristically, sits on its flexed legs and draws the head back in a "star-gazing" position (Fig. 7.11). Retraction of the head is due to paralysis of the anterior muscles of the neck. Soon after this stage, the chicken loses the ability to stand or sit upright and topples to the floor, where it lies with the head still retracted in many instances.

The body temperature drops to as low as 96° F. (Vedder and Clark, 1912). A progressive decrease in the respiratory rate

FIG. 7.11 — Typical "star-gazing" pose displayed by chick suffering from thiamine deficiency.

occurs. The adrenal glands hypertrophy more markedly in females than males. The cortex is apparently affected to a greater extent than the medulla. Apparently the degree of hypertrophy in the adrenals determines the degree of edema of the tissues (McCarrison, 1918). In the chicken, edema occurs largely in the skin (Krause, 1922). It has been observed that the epinephrine content of the adrenals increases as this organ hypertrophies. Atrophy of the genital organs also occurs in chickens affected with thiamine deficiency. This is more pronounced in the testes than in the ovaries. The heart shows a slight degree of atrophy. The right side of the heart is frequently dilated, the auricle being more frequently affected than the ventricle. Atrophy in the stomach and intestinal walls may be sufficiently severe to be noted without the aid of a microscope.

Treatment. Chickens suffering from thiamine deficiency respond, in a matter of a few hours, to oral administration of the vitamin. Since thiamine deficiency causes extreme anorexia, supplementing the feed with the vitamin is not a reliable treatment until after the chickens have recovered from the acute deficiency via oral administration of thiamine.

RIBOFLAVIN (VITAMIN B₂) AND RIBOFLAVIN DEFICIENCY

Riboflavin forms the active part of over a dozen enzyme systems in the body. The

noted of these is the "yellow oxi-
dase enzyme." Other important ribo-
flavin containing enzymes are: cytochrome
reductase, diaphorase, xanthine oxidase,
L- and D-amino acid oxidases, and hista-
minase, all of which are vitally associated
with the oxidation-reduction reactions in-
volved in cell respiration.

Chemical nature and occurrence. Ribo-
flavin is a heat-stable, water-soluble com-
pound, containing an isoalloxazine nucleus
and a ribose side chain. It is subject to
destruction by light, especially in alkaline
solution. It is normally a yellow substance,
solutions of which give off a greenish
fluorescence when exposed to blue or ultra-
violet light. Treatment of solutions of
riboflavin with reducing agents converts it
to the colorless form (leuco-form), which
shows no fluorescence. The greenish color
of egg albumen is due to the riboflavin
present in it. Riboflavin is present in milk
by-products, alfalfa, grass meals, and liver.
It is synthesized by yeasts and bacteria.
Riboflavin for commercial feed supple-
ments is produced by chemical synthesis
and by fermentation of waste materials
with various bacteria, especially *Clostrid-
ium acetobutylicum.*

Requirements. The riboflavin require-
ments of chickens and turkeys are pre-
sented in Table 7.1. The requirements of
chickens were confirmed by Hill et al.
(1954).

Symptoms and Pathology

Symptoms of riboflavin deficiency in the
chick were first reported by Norris et al.
(1930), Bethke et al. (1931), and Lepkov-
sky and Jukes (1936). When chicks are
fed a diet deficient in riboflavin, they grow
very slowly, become weak and emaciated;

their appetite is fairly good, and diarrhea
develops between the first and second
week. The chicks do not walk except when
forced to do so, and then frequently walk
upon their hocks with the aid of their
wings. The toes are curled inward (Fig.
7.12), both when walking and when rest-
ing on their hocks. The chicks are usually
found in a resting position. The wings
often droop as though it were impossible
for the chicks to hold them in the normal
position. The leg muscles are atrophied
and flabby, and the skin is dry and harsh.
Young chicks in advanced stages of defi-
ciency do not move around but lie with
their legs sprawled out.

Postmortem examination does not show
any marked abnormalities of the internal
organs, nor does bacteriological exami-
nation reveal any specific infection of the
blood or other internal organs. In some
cases, the thymus shows congestion and pre-
mature atrophy.

According to Davis et al. (1938a,
1938b) and Lepkovsky et al. (1938), the
only symptoms noted in a deficiency of
riboflavin in the diet of hens are decreased
egg production, increased embryonic mor-
tality, and an increase in the size and the
fat content of the liver. The hatchability
of eggs becomes poor within 2 weeks after
hens are fed a riboflavin-deficient diet,
but the hatchability improves to nearly
normal within 7 days after adequate
amounts of riboflavin are added to the
diet. The embryos which fail to hatch
from the eggs of hens on diets low in this
vitamin are dwarfed, and show a high in-
cidence of edema, degeneration of the
Wolffian bodies, and a characteristically
defective down. This type of down is re-
ferred to as "clubbed," and results from a

FIG. 7.12 — Riboflavin deficiency
(curly toe).

failure of the down feathers to rupture the sheaths; this causes the feathers to coil and take the shape of a French knot.

Riboflavin deficiency in the young turkey is characterized by poor growth and incrustations in the corners of the mouth and on the eyelids. Severe dermatitis of the feet and shanks, marked by edematous swelling, desquamation, and deep fissures, appears in some of the deficient poults (Heuser, 1935; Bethke and Record, 1942; McGinnis and Carver, 1947). It is noted that these symptoms of riboflavin deficiency in the turkey are similar to those of pantothenic acid deficiency in the chicken.

In severe cases of riboflavin deficiency, chicks show a very marked swelling and softening of the sciatic and brachial nerves. The sciatic nerves usually show the most pronounced effects. They may reach a diameter 4 to 5 times the normal size.

Phillips and Engel (1938) reported that histologic examinations of the affected nerves show definite degenerative changes in the myelin sheaths of the main peripheral nerve trunks. This may be ac-

companied by axis cylinder swelling and fragmentation, Schwann cell proliferation, myelin changes, gliosis, and chromatolysis in the spinal cord. In cases of curled-toe paralysis, degeneration of the neuro-muscular end plate and muscle tissues is often found. This indicates that riboflavin is necessary for the normal functioning of the nervous system of the growing chick. Riboflavin is probably also essential for myelin metabolism of the main peripheral nerve trunks. No gross dystrophy develops, although muscle fibers are, in some cases, completely degenerated. The sciatic nerve exhibits myelin degeneration in one or more of its branches. Similar changes are apparent in the brachial nerve trunks.

In the case of embryos which fail to hatch from eggs laid by hens fed riboflavin-deficient diets, the nervous system shows degenerative changes very much like those described in riboflavin-deficient chicks (Engel et al., 1940).

Treatment of deficiency. Chicks receiving rations only partially deficient in riboflavin may recover spontaneously, indi-
FIG. 7.13 — A 35-day-old poult showing riboflavin deficiency with curled-toe paralysis. (Richardson, Tex. Agr. Exper. Sta.)
FIG. 7.15 — Dermatosis of pantothenic acid deficiency in the chick.

and severe edema are symptoms of pantothenic acid deficiency in the developing chick embryo (Beer et al., 1963).

The symptoms of pantothenic acid deficiency in chicks are difficult to differentiate from those of biotin deficiency. Robblee and Clandinin (1950) reported that deficiencies of pantothenic acid and biotin result in dermatitis, broken feathers, perosis, poor growth, and mortality. Pantothenic acid deficient chicks are characterized by retarded and rough feather growth (Norris and Ringrose, 1930). The chicks are emaciated, and definite crusty scablike lesions appear in the corners of the mouth. The margins of the eyelids are granular, and small scabs develop on them. The eyelids are frequently stuck together by a viscous exudate; they are contracted, and vision is restricted (Fig. 7.15). In some cases the feathers are lost from the head. There is a slow sloughing of the keratinizing epithelium of the skin. The outer layers of skin between the toes and on the bottoms of the feet sometimes peel off, and small cracks and fissures appear at these points. These cracks and fissures enlarge and deepen, and the chicks move about very little. In some cases the skin layers of the feet of deficient chicks thicken and cornify, and wartlike protuberances develop on the balls of the feet.

Postmortem examination shows the presence of a puslike substance in the mouth and an opaque, grayish-white exudate in the proventriculus (Ringrose et al., 1931). The liver is hypertrophied and may vary in color from a faint yellow to a dirty yellow. The spleen is slightly atrophied. The kidneys are somewhat enlarged. The nerves and myelinated fibers of the spinal cord show myelin degeneration (Phillips and Engel, 1939). These degenerating fibers occur in all segments of the cord down to the lumbar region.

Gillis et al. (1948) showed that the amount of pantothenic acid in the feed for a hen has a definite effect on the hatchability of the eggs produced. Embryonic mortality was high when the hens were fed a diet low in pantothenic acid. Most of the mortality occurred during the last 2 or 3 days of the incubation period.

Treatment of deficiency. The symptoms of pantothenic acid deficiency appear to be completely reversible, if not too far advanced, by oral treatment or injection with the vitamin, followed by restoration of an adequate level (Table 7.1) of pantothenic acid in the diet.

Pantothenic acid deficiency, in sufficient severity to cause characteristic symptoms of the deficiency, has not been demonstrated to occur under field conditions. Robertson et al. (1949) noted that the disease known as "stunted chick disease" exhibits many of the symptoms characteristic of pantothenic acid deficiency. However, substitution of 5 per cent liver meal for 5 per cent meat scrap in the ration or injection of the chicks with 100 μg. of pantothenic acid failed to provide any protection in the course of the disease.

On the other hand, another field disease has been observed which may indicate a deficiency of pantothenic acid in chicken breeder rations under certain conditions. In this disease, first noted by Hill (1954), egg production and hatchability of fertile eggs are normal, but the chicks are underweight, weak, and may suffer up to 50 per cent mortality during the first 24 hours after hatching. Hill (1954) and Fisher and Hudson (1956) found that injection of the chicks with a mixture of B vitamins, or with pantothenic acid alone,

mature poultry with niacin, and no deficiency symptoms have been described.

Treatment. Supplementation of a deficient ration with the required amounts of niacin, as shown in Table 7.1, usually brings about rapid recovery from all symptoms of deficiency, including the hock enlargements and bowed legs, in young chicks, ducklings, or poults. Niacin supplementation usually has little or no effect upon cases which have progressed to the extent that the tendon has slipped from its condyles (perosis), or upon advanced cases of "enlarged hock disorder" in adult tom turkeys.

PYRIDOXINE (VITAMIN B₆) AND PYRIDOXINE DEFICIENCY

Pyridoxine is required in several enzymes, particularly those concerned with deamination, transamination, and decarboxylation of amino acids. The coenzymes for these reactions are known as pyridoxal phosphate and pyridoxamine phosphate.

Chemical nature and occurrence. Pyridoxine, like niacin, is a stable member of the vitamin B complex containing a pyridine nucleus and a primary alcohol grouping. Pyridoxal and pyridoxamine are derivatives of pyridoxine containing an aldehyde and amine group, respectively, instead of the alcohol group. Most feedstuffs are fairly good sources of pyridoxine (Schneider et al., 1939), thereby making it unnecessary to supplement practical poultry rations with this vitamin.

Requirements. Relatively little research work has been done on the pyridoxine requirements of poultry. The requirements based upon published work are shown in Table 7.1. A number of studies of pyridoxine requirements have been conducted by Fuller and Kifer, 1959; Fuller and Dunahoo, 1959; and Fuller et al., 1961. Lucas et al. (1946) found that crossbred chicks (Rhode Island Red × Barred Plymouth Rock) showed a considerably higher requirement for pyridoxine than had previously been found by Hogan et al.

(1941) and by Briggs et al. (1942b) for White Leghorn chicks. This suggests that the pyridoxine requirement may vary with different breeds and families or, as indicated under the discussion of the niacin-tryptophan-pyridoxine interrelationship, may depend upon the levels of certain other nutrients in the diet.

Symptoms

Pyridoxine deficient chicks show depressed appetite, poor growth, and characteristic nervous symptoms. The chicks show jerky, nervous movements of the legs when walking and often undergo extreme, spasmodic convulsions which usually terminate in death. During these convulsions, chicks may run aimlessly about, flapping their wings and falling to their sides or rolling completely over on their backs, where they perform rapid jerking motions with their feet and heads. These symptoms may be distinguished from those of encephalomalacia by the relatively greater intensity of activity of the chicks during a seizure resulting from pyridoxine deficiency, which results in complete exhaustion and often in death.

In adult birds, pyridoxine deficiency causes marked reduction of egg production and hatchability as well as decreased feed consumption, loss of weight, and death (Cravens et al., 1943, 1946).

BIOTIN AND BIOTIN DEFICIENCY

Although biotin is a dietary requirement and a deficiency of this vitamin produces very severe lesions, no definite metabolic role has been established for biotin in poultry.

Chemical nature and occurrence. Biotin is a sulfur-containing, complex member of the vitamin B complex. It is present in common feedstuffs in sufficient amounts to meet the biotin requirements of poultry without the use of special biotin-rich supplements. Liver meal, yeast, milk byproducts, and molasses are rich sources.

Unheated egg white contains a protein, avidin, which is capable of reacting with

FIG. 7.16 — A biotin-deficient chick.

biotin in the intestinal tract of chicks or other animals, rendering the dietary biotin unavailable to the animal and thereby creating a biotin deficiency. Thus, only under the unusual conditions in which raw egg white is used in a poultry ration, is a deficiency of biotin likely to be encountered.

Requirements. Only the requirement for starting chicks has been studied. This is given in Table 7.1.

Symptoms and Pathology

In biotin deficiency, the dermatitis of the feet and the skin around the beak and eyes (Fig. 7.16) is similar to that described under the section on pantothenic acid. Thus, in making a differential diagnosis between biotin and pantothenic acid deficiency, it is usually necessary to examine the composition of the ration fed and decide which vitamin is more likely to be deficient in the ration. This can be checked by feeding the ration to two groups of chicks, supplementing the feed for one group with biotin, the other with pantothenic acid.

Couch et al. (1948) reported that congenital perosis, ataxia, and characteristic skeletal deformities developed when the hens were fed a low-biotin diet which did not favor intestinal synthesis of the vitamin. The deformities were prevented by adding biotin to the diet. These embryonic deformities consisted of a shortened tibiotarsus which was bent posteriorly, a much shortened tarsometatarsus, shortening of the bones of the wing and of the skull, and shortening and bending of the anterior end of the scapula.

According to Cravens et al. (1942, 1944), embryos from hens fed biotin-deficient diets developed syndactylia, an extensive webbing between the third and fourth toes. These workers also observed that a large number of the embryos which failed to hatch were chondrodystrophic, and were characterized by a reduced size, a parrot beak, severely crooked tibia, and/or a much shortened or twisted tarsometatarsus. One peak of embryonic mortality occurred during the first week of incubation, a second during the last 3 days.

Perosis is also a characteristic deficiency symptom of biotin avitaminosis. This has been demonstrated by a number of workers including McElroy and Jukes (1940), Jukes and Bird (1942), and Richardson et al. (1942). Symptoms of perosis are described in Chapter 6 under Manganese.

Treatment. If biotin deficiency is observed in a poultry flock, one should first investigate the possibility of the presence of uncooked egg white in the diet, since biotin deficiency is very difficult to produce, even with highly purified feed ingredients, unless raw egg white (avidin) is added to the diet. Biotin supplementation of a diet containing raw egg white might not correct the deficiency unless the level of biotin used is in excess of the biotin-combining capacity of the egg white. Under these conditions, injection of a few micrograms of biotin should produce recovery, which should be maintained by exclusion of egg white from the diet.

FOLIC ACID (FOLACIN) AND FOLIC ACID DEFICIENCY

Folic acid is a part of the enzyme systems concerned in "single carbon" metabo-

lism. In this manner, it is involved in the synthesis of purines and of the methyl groups of such important metabolites as choline, methionine, and thymine. Because of this, folic acid is required for normal nucleic acid metabolism and for the formation of the nucleo-proteins required for cell multiplication.

Chemical nature and occurrence. Folic acid is a fairly stable member of the vitamin B complex. Its chemical structure contains three distinct parts: (1) a pterin (related to xanthopterin, the pigment in yellow butterfly wings), (2) *p*-amino benzoic acid (PABA), and (3) glutamic acid. The chemical name for folic acid is pteroylglutamic acid. An important derivative of folic acid is the citrovorum factor (leucovorin or folinic acid), which resembles folic acid except that it contains four additional hydrogen atoms and a formyl group. The research evidence indicates that the citrovorum factor is the metabolically active form of folic acid. Much of the folic acid in natural feedstuffs is conjugated with varying numbers of extra glutamic acid molecules. In these bound forms, it is inactive for the assay microorganisms and as a metabolite in the animal body. However, chicken and turkey pancreas, liver, and kidney contain enzymes capable of releasing free folic acid and free citrovorum factor from the respective conjugates. The activities of these "conjugases" are influenced by a number of other factors (Hill and Scott, 1951, 1952a, 1952b).

Yeast, liver, alfalfa meal, and soybean meal are rich sources of folic acid, while corn is a relatively poor source. The high level of soybean meal in practical poultry rations is largely responsible for the fact that these rations need not be supplemented with special sources of this vitamin. Bearse *et al.* (1955b) found that with corn as the cereal portion of a chick starter ration, chicks developed symptoms of folic acid deficiency when soybean meal was replaced with herring meal as the protein supplement. The deficiency was prevented

either by substitution of soybean meal for herring meal, by substitution of milo for corn, or by supplementing the herring meal-corn ration with folic acid.

Requirement. The results of studies on the folic acid requirements of chickens and poults are summarized in Table 7.1.

Symptoms and Pathology

Folic acid deficiency in chicks is characterized, grossly, by poor growth, very poor feathering, an anemic appearance (Robertson *et al.*, 1946), and perosis (Daniel *et al.*, 1946). McGinnis *et al.* (1942) discovered that a factor, later shown by Frost *et al.* (1946) to be the *L. casei* factor (folic acid), is required for pigmentation in the feathers of Rhode Island Red and Black Leghorn chicks. Thus, folic acid, lysine, and iron (see Chapter 6) appear to be required for prevention of white feathering in colored poultry. A deficiency in the breeding ration causes a marked increase in embryonic mortality. The embryos usually die soon after pipping the air cell. According to Sunde *et al.* (1950a, 1950b), a deformed beak and bending of the tibiotarsus are symptoms of the embryonic deficiency. Poults show a characteristic "cervical paralysis" (Fig. 7.17), and die within 2 days after the onset of these symptoms unless folic acid is administered immediately. Poults show only a slight anemia.

Folic acid deficiency in chicks results in megaloblastic arrest of erythrocyte formation in the bone marrow, which results in a severe macrocytic anemia as one of the first symptoms in chicks. White cell formation is also reduced, which causes a marked agranulocytosis. Further evidence that folic acid is necessary for cell mitosis is supplied by these discoveries: (1) that oviduct growth is not increased in estrogen-treated chicks unless the diet is supplemented with folic acid (Hertz, 1945; Haque *et al.*, 1949) or, preferably, with the citrovorum factor (Kline and Dorfman, 1951); (2) that the growth of the chicken embryo is inhibited by very

FIG. 7.17 — Folic acid deficiency, showing "straight neck" paralysis. (Richardson and Hogan, Ma. Agr. Exper. Sta.)

small amounts of the folic acid antago-nist, 4-aminofolic acid (Karnofsky *et al.*, 1949), the inhibition being reversed by adding citrovorum factor (Cravens and Snell, 1950); and (3) that Rous chicken sarcoma is inhibited completely either by folic acid deficiency or by feeding 4-amino-folic acid (Little *et al.*, 1948).

Folic acid-choline interrelationship. In the presence of adequate folic acid in the diet, only approximately 260 mg. of cho-line are required to prevent perosis in chicks. But when the diet is deficient in folic acid, an increase in the level of choline causes some improvement in the incidence and severity of perosis, whereas levels up to 900 mg. of choline per pound of diet fail to prevent this disorder com-pletely (Young *et al.*, 1955).

Treatment. A single intramuscular in-jection of 50 or 100 µg. of pure pteroyl-glutamic (folic) acid causes a peak reticu-locyte response (70 per cent) within 4 days in severely anemic, folic acid-deficient chicks (Robertson *et al.*, 1947). The hemo-globin values and growth rates return to normal within one week. Oral administra-tion of 50 µg. of folic acid was much less effective, whereas the addition of 500 µg. of folic acid per 100 gm. of feed caused re-

covery comparable to that obtained with injection of the vitamin.

VITAMIN B$_{12}$ (COBALAMIN) AND VITAMIN B$_{12}$ DEFICIENCY

Vitamin B$_{12}$ is concerned in nucleic acid synthesis, methyl synthesis, carbohydrate metabolism, fat metabolism, and mainte-nance of glutathione blood levels. Al-though evidence exists that vitamin B$_{12}$ is concerned in protein metabolism, Henry and Kon (1956) suggest that this is not due to an effect upon protein utilization but to the effect of this vitamin in aiding the synthesis of the methyl group needed for the formation of methionine.

Chemical nature and occurrence. Vita-min B$_{12}$ is the most recently identified member of the water-soluble, B-complex group of vitamins. It has a complicated structure of organic moieties surrounding a central cobalt atom. Vitamin B$_{12}$ con-tains a cyano group and is known chemi-cally as cyanocobalamin. Other active cobalamins contain such anions as hy-droxy, chloro, bromo, sulfato, nitro, or nitrito groups in place of the cyano group. Thus, vitamin B$_{12a}$ and vitamin B$_{12b}$ have been shown to be hydroxycobalamin, and vitamin B$_{12c}$ is nitritocobalamin.

The primary occurrence of vitamin B_{12} in nature appears to be solely the result of microbial synthesis. Little or no evidence has been obtained to show that this vitamin can be produced by higher plants, and there is no evidence of its synthesis in animal tissues. The vitamin is found in all foods of animal origin. Early recognition of this accounts for its being referred to as the "animal protein factor" (APF). The best poultry feed sources are fish solubles, fish meal, liver meal, meat scraps, and the commercial vitamin B_{12} feed supplements which are produced by special fermentations using vitamin B_{12}-synthesizing microorganisms.

Requirements. The vitamin B_{12} requirements of poultry depend upon the levels of several other nutrients in the diet. The relationship between vitamin B_{12} and pantothenic acid has been discussed earlier. Excess protein in the diet increases the need for vitamin B_{12}. The vitamin B_{12} requirement also appears to depend upon the levels of choline, methionine, and folic acid in the diet and is interrelated with ascorbic acid metabolism in the body. The vitamin B_{12} requirements of chicks and hens, under normal conditions, are shown in Table 7.1.

Symptoms and Pathology

Symptoms of vitamin B_{12} deficiency are slow growth, decreased efficiency of feed utilization, mortality, and reduced hatchability. No characteristic symptoms specific for vitamin B_{12} deficiency have been demonstrated in growing or mature poultry. Perosis may occur in vitamin B_{12}-deficient chicks or poults when the diet lacks choline, methionine, or betaine as sources of methyl groups. Addition of vitamin B_{12} may prevent perosis under these conditions, because of its effect upon the synthesis of methyl groups. Kline (1955) demonstrated that in vitamin B_{12}-deficient pullets maintained on a diet low in choline and methionine, oviduct response to treatment with diethylstilbestrol was significantly lower than in pullets receiving vitamin B_{12}. McGinnis et al. (1948) reported that a deficiency of vitamin B_{12} caused an increased nonprotein nitrogen level in the blood of chicks, which was reduced to normal by feeding a vitamin B_{12}-rich liver concentrate. Olcese et al. (1950) reported a peak in embryonic mortality at the seventeenth day of incubation of eggs from vitamin B_{12}-deficient hens. They reported a myoatrophy of the legs in the vitamin B_{12}-deficient embryos (Fig. 7.18). Other anomalies associated with vitamin B_{12} deficiency in the embryos were hemorrhages and perosis.

Treatment. Peeler et al. (1951) showed that the intramuscular injection of 2 μg. of vitamin B_{12} per hen caused the hatchability of eggs from the vitamin B_{12}-deficient hens to increase from approximately 15 per cent to 80 per cent within one week. Chin et al. (1958) found that the addition of 4 mg. of vitamin B_{12} per ton of a breeding ration was sufficient to maintain maximum hatchability and for the production of chicks having sufficient stores of vitamin B_{12} to prevent any deficiency of this vitamin during the first few weeks of life. Similar injections of young chicks, followed by a similar supplementation of the chick ration, also will correct a vitamin B_{12} deficiency in chicks. Lillie et al. (1949) showed that when eggs laid by hens deficient in vitamin B_{12} were injected with the crystalline vitamin, hatchability and subsequent growth of the chicks were improved.

CHOLINE AND CHOLINE DEFICIENCY

Choline is present in acetylcholine, in the body phospholipids, and acts as a methyl source in the synthesis within the body of methyl-containing compounds such as methionine, creatine, and N-methylnicotinamide. Acetylcholine is the chemical substance produced at the termination of the parasympathetic nerves upon stimulation and is responsible for their effects, such as the vagus inhibition of the heart. Some sympathetic nerves also are cholinergic. Choline, per se, does not act as a methyl donor, but first must be oxidized to the compound, betaine, which can

FIG. 7.18 — Embryos with myoatrophy, caused by deficiency of vitamin B₁₂ (left and right), and normal embryo (center). (Olcese, Texas A. and M. College System.)

then donate one of its three methyl groups to a methyl acceptor such as homocysteine or glycocyamine, for the formation of methionine or creatine, respectively.

Chemical nature and occurrence. Choline is N-trimethyl ethanolamine. It can be synthesized in the body of the chick by the further methylation of N-monomethyl ethanolamine. The methyl groups may arise from methionine, betaine, or may be synthesized de novo through a mechanism involving vitamin B₁₂.

Poultry feedstuffs rich in choline are liver and glandular meal, fish meal and fish solubles, yeast, distillers solubles, and soybean meal.

Requirement. The choline requirements, under normal conditions, are presented in Table 7.1.

Symptoms and Pathology

In addition to poor growth, the outstanding symptom of choline deficiency in chicks and poults is perosis. Perosis is first characterized by pinpoint hemorrhages and a slight puffiness about the hock joint. This is followed by an apparent flattening of the tibiometatarsal joint which is caused by a rotation of the metatarsus (Milne,

1936). The metatarsus continues to twist and may become bent or bowed so that it is out of alignment with the tibia. When this condition exists, the leg cannot adequately support the weight of the bird. The articular cartilage is displaced, and the tendon of Achilles slips from its condyles.

According to Abbott and DeMasters (1940), when laying pullets are fed diets deficient in choline, increased mortality, increased abortion of egg yolks from the ovaries, and an increase in the percentage of fatty acids in the liver result. The percentage of fatty acids in the livers of choline-deficient chickens is much higher in females than in males. However, other evidence shows that choline deficiency is rare in adult chickens and turkeys fed practical rations.

Treatment. If a diagnosis of choline deficiency is noted in chicks or poults before the severe symptoms of perosis have developed, the deficiency can be cured by supplementing the ration with sufficient choline to meet the requirements indicated in Table 7.1. Once the tendon has slipped in chicks or poults suffering from choline deficiency, the damage is irreparable.

VITAMIN C, INOSITOL, p-AMINOBENZOIC ACID AND LIPOIC ACID

Vitamin C (ascorbic acid) is synthesized in adequate amounts by all species of poultry (Carrick and Hauge, 1925; Hart et al., 1925b).

Inositol has been known for years to be an essential nutrient for certain yeasts and other microorganisms. Evidence from a number of studies indicates that inositol is not required in the diet of poultry.

p-Aminobenzoic acid is a part of the folic acid molecule. Thus, the presence of this compound in the diet aids the in-

testinal microorganisms in their synthesis of folic acid, which could benefit the chicken or turkey if the diet happened to be deficient in folic acid.

Lipoic acid (also referred to as protogen or thioctic acid) is a newly discovered metabolite concerned in oxidative decarboxylation in carbohydrate (pyruvate) metabolism. Lipoic acid is apparently synthesized in adequate amounts by the chick. Stokstad et al. (1953), Supplee et al. (1956), Morrison and Norris (1956), and others have shown that the addition of lipoic acid to purified diets for chicks fails to cause any improvements in growth.

8

Pullorum Disease

In 1899 the etiological agent of pullorum disease was discovered by Rettger (1900). He first described the disease as a "Fatal Septicemia of Young Chicks," but later (1909) he designated it as "White Diarrhea." However, in that same year, in a subsequent report, Rettger and Stoneburn (1909) applied the term "Bacillary White Diarrhea" in order to distinguish it from other avian diseases which might be classified under a common terminology of "White Diarrhea" as was reported by Jones (1911).

In 1929 at the Second Annual Meeting of Investigators and Workers in Bacillary White Diarrhea Control, Rettger and Plastridge (1932), at the suggestion received from a research member of the Pennsylvania Department of Agriculture, proposed that the term "Pullorum Disease" be substituted for "Bacillary White Diarrhea." This new terminology was internationally adopted because of its brevity, specificity, and appropriateness in designating a disease entity which af-

fected not only chicks but also mature poultry and fowl other than chickens.

HISTORY

The isolation of the causative agent of pullorum disease by Rettger (1900) in 1899 gave an insight into the serious chick-raising problem reported in the lay press (E. A. H., 1905; Gifford, 1905; Graham, 1904) which appeared before and after the epoch-making discovery. At the close of the nineteenth century, this malady was considered a very serious menace to the poultry industry. During the first decade of the twentieth century, investigators definitely proved that pullorum disease was an egg-borne infection. The cycle of infection involved an infected hen laying infective eggs, hatching infected chicks, which could develop into mature infected stock.

During the second decade, Jones (1913b), and later others (Gage et al., 1914; Rettger et al., 1914), announced the practical application of the macroscopic

tube agglutination test for the detection of "carriers" of the organism. The application of this test in the control and eradication of the disease was carried out rather extensively in some of the eastern states so that toward the close of the second decade, official state testing programs were inaugurated.

The progressive development and expansion of the baby chick industry through more modern methods of incubation, brooding, and transportation have influenced the dissemination of the disease. Incubator transmission has been, and still is, an important factor in the spread of pullorum disease from plant to plant by means of flock replacements.

Another event which has influenced the pullorum status throughout the world was the organization of the Conference of Investigators and Workers in Bacillary White Diarrhea Control (W. R. H., 1928), composed first of representatives from the New England states and later (Anon., 1930) enlarged to include other eastern states and provinces in Canada. This conference has made a concerted effort to bring about standardization and uniformity of methods and to stimulate an interest in the practical eradication of the disease from breeding flocks.

The Conference of Research Workers in Animal Diseases of North America (Anon., 1933) formulated "Standard Methods of Diagnosis of Pullorum Disease in Barnyard Fowl" which were adopted by this organization and also by the United States Livestock Association in 1932. These methods of diagnosis have served as valuable guides in combating pullorum disease.

Schaffer et al. (1931) announced the development of the modified whole-blood method in which stained antigen is employed. In view of its apparent simplicity, it has been widely used with the result that many infected birds have been detected, and thus their removal from breeding flocks was made possible.

The United States Department of Agriculture inaugurated the National Poultry Improvement Plan which represents a national effort to control and eradicate pullorum disease in poultry flocks (National Poultry Improvement Plan, 1941).

The above-mentioned events point out that during the past years the poultry industry has been made more secure through the publication of these scientific facts and through the adoption of official federal and state plans which are being employed to combat pullorum disease.

DISTRIBUTION AND ECONOMIC IMPORTANCE

Pullorum infection is world-wide in its distribution. It is likely to be found wherever poultry is being raised. Prior to the date the organism was discovered by Rettger (1900), the disease had been observed in the United States and Canada by those engaged in poultry husbandry. Later reports (Reis and Nobrega, 1936) revealed the recognition of the disease in England, different parts of continental Africa, Asia, Australia, Europe, Japan, Korea, and South America.

Economic losses of serious proportions were reported during the last decade in the nineteenth century. As the poultry industry developed, especially in the breeding and hatching phases, the incidence of the disease was permitted to become greater, and the infection was disseminated more widely throughout the United States and Canada. During a later period this likewise was true in other countries.

Losses from the disease may be experienced through severe chick mortality, reduced fertility and hatchability, retardation in growth, reduced egg production, increased mortality among adult stock, and a reduction in the sales quality of the stock.

Rettger (1900, 1901) in his early observations of the disease found that among hen-reared and among artificially brooded chicks, total mortalities might approximate 85 per cent during the first four weeks of age. Later reports (Jones, 1911; Kaupp, 1917) reveal similar or even higher
FIG. 8.1 — (1) Isolated colony on primary culture. Meat extract agar. 40 hours old. ×15. (2) Isolated colony on primary culture. Liver infusion agar, 40 hours old. ×15. (3) Cells in a smear prepared from colony illustrated in 1. ×1,200. (4) Cells in a smear prepared from colony illustrated in 2. ×1,200.

be profitable and that variations in production may be expected depending upon the localization and degree of infection. It is generally accepted that pullorum infection may impair production and should for that reason, as well as for other reasons, not be tolerated in a flock.

Through the inauguration of official control programs and the establishment of official grades for pullorum-tested flocks, it has been made possible to identify flocks as to their official pullorum disease status and thereby afford the buying public an opportunity to buy stock of the highest quality. An abundance of pullorum-free stock is available at the present time in most areas and should be adequate to meet the demands of the buying public.

ETIOLOGY

Pullorum disease is a bacterial infection caused by an organism which Rettger (1900, 1909) first designated as a bacillus and a few years later named *Bacterium pullorum*.

More recently the systematic bacteriologist has classified the etiological agent in the "Salmonella" genus, and at the present time, the organism is recognized as *Salmonella pullorum*. It has many features in common with other members of the Salmonella group.

The organism is a long, slender rod (.3–.5 × 1–2.5μ) with slightly rounded ends (Fig. 8.1–3). It readily stains with ordinary basic anilin dyes and is Gram-negative. The cells occur singly, with chains of more than two bacilli being rarely found. An occasional filament and large cell may be found in smear preparations. It is nonmotile, nonliquefying, nonchromogenic, nonsporogenic, and facultatively anaerobic. Optimum growth occurs at 37° C. and under normal atmospheric conditions. On meat extract agar (pH 7.0–7.2) heavily seeded with inoculum, the colonies appear discrete, smooth, glistening, homogeneous, entire, dome-shaped, transparent, and varying in form from round to angular (Fig. 8.1–1). On chicken infusion agar, the growth is slightly more luxuriant, with colonies possessing a lesser degree of transparency. On liver infusion agar, the growth is even more luxuriant and markedly translucent (Fig. 8.1–2 and 4). Congested colonies remain small (1 mm. or less), but isolated colonies may attain a diameter of 3 to 4 mm. or more. Surface markings may appear as the colony increases in size and age, but as a rule the young colony on a heavily seeded plate changes little with age.

The following substances are attacked

with acid and with or without gas production: arabinose, dextrose, galactose, levulose, mannite, mannose, rhamnose, and xylose. Substances not attacked include adonite, dextrin, dulcitol, erythrol, glycerol, inositol, inulin, lactose, raffinose, saccharose, salicin, sorbite, and starch. Maltose is attacked very infrequently as has been reported by Edwards (1928), Hendrickson (1927), Hinshaw (1941), and Pacheco and Rodrigues (1936). However, the results in some instances were attributed to the materials and methods employed for the cultivation of the organism. Edwards (1928) concluded that acid production in maltose by *S. pullorum* was made possible through the hydrolization of the sugar by the alkali that slowly developed upon prolonged incubation. Hendrickson (1927) observed that when serum water was used for sugar base, maltose was fermented by *S. pullorum*. Pacheco and Rodrigues (1936) encountered similar findings and claimed the acid production by the organism was the result of serum-enzyme hydrolysis of the sugar. Van Roekel (1935) reported a laboratory strain which had been considered as a maltose nonfermenting organism, but after a lapse of several years since its original isolation it acquired and retained the ability to attack maltose. No plausible explanation could be given for the sudden change in the maltose-fermenting characteristic. Subsequent investigations (Van Roekel *et al.*, 1937) revealed that strains which possessed a potential tendency to ferment maltose could be identified by cultivating them in a maltose-peptone solution for a period of time Strains undergoing a change in behavior toward maltose would exhibit red and white colonies when plated on a modified Endo's medium (maltose substituted for lactose). Strains that produced both maltose-fermenting and nonmaltose-fermenting colonies exhibited only nonmaltose-fermenting colonies after being subjected to animal passage. An apparently pure maltose-fermenting strain did not lose this property when subjected to animal passage. It is apparent that *S. pul-*

lorum may display variation in its behavior in the fermentation of maltose, and for that reason this sugar cannot be regarded of value in the identification of the organism. Variation in the behavior of some strains may be observed occasionally, especially in regard to gas production. Litmus milk remains practically unchanged. Indol and acetylmethyl carbinol are not formed. Hydrogen sulfide is produced, and nitrates are reduced.

The organism can be cultivated on special media such as dextrose-lactose agar (Mallmann and Snyder, 1929), brilliant green agar (Mallmann, 1929), Endo's agar, cysteine gelatin (Hinshaw, 1941), and sodium tartrate and mucate media (Mallmann, 1931b) which may be of value in the differentiation from other organisms. Bushnell and Porter (1945) tested several types of media for the cultivation and isolation of *S. pullorum*. They concluded that no single medium used proved satisfactory for isolation of *S. pullorum*. In the selection of the medium for the isolation of *S. pullorum* consideration must be given to the source of material to be examined. In isolating *S. pullorum* from the intestine, desoxycholate citrate, bismuth sulfite, and S-S agar were found to be the most satisfactory. Tetrathionate broth was recommended as an enrichment medium.

Growth studies of *S. pullorum* strains in different media revealed that the rate of growth was in a declining order for nutrient broth. one per cent tryptose-water, and a synthetic medium (Schoenhard and Stafseth, 1953). Other workers have demonstrated that the organism is capable of synthesizing glutamic acid and alanine when propagated in synthetic media containing threonine (Jones and Holtman, 1953). Also the virulence of the organism was maintained as readily in the synthetic medium as by animal passage (Gilfillan *et al.*, 1955). The rate of growth of *S. pullorum* could be increased markedly by the addition of yeast extract to trypticase soy agar (Stokes and Bayne, 1957). The authors suggest that the addition of yeast

extract to selective agars may be helpful in the isolation of slow-growth Salmonella.

Reference to the literature (Hinshaw, 1941; Pacheco and Rodrigues, 1936; and Rettger and Plastridge, 1932) reveals that a disagreement concerning the results of the biochemical behavior of *S. pullorum* is to be found; especially is this true among European and American workers. The former for the most part are inclined to regard *S. pullorum* and *S. gallinarum* as identical species. This is difficult to comprehend when certain areas in the United States are observed to be relatively free of fowl typhoid as based on field and laboratory observations, whereas pullorum disease is more prevalent. This statement is based on diagnoses obtained by the standard criteria employed in differentiating these two diseases.

While *S. pullorum* is generally accepted as being a stable distinct species, Plastridge and Rettger (1930, 1932), Mallmann (1932), and Van Roekel (1935) have observed that the organism may vary markedly in many of its characteristics (Fig. 8.2–5 to 8). The toxicogenic properties of *S. pullorum* were investigated by Hanks and Rettger (1932), who observed that *S. pullorum* cells contained an extractable heat-resistant poison which is highly toxic for rabbits and is capable of killing guinea pigs and mice. Chicks revealed no noticeable symptoms of illness, regardless of the route by which the material was introduced. They concluded that pullorum disease appears to be a septicemia rather than a toxemia.

The antigenic composition of *S. pullorum*, according to the Kauffmann-White schema (Salmonella Subcommittee, 1934), consists only of the O-antigen. Its antigenic structure is similar to that of *S. gallinarum*. However, the O-antigen of *S. pullorum* and *S. gallinarum* has something in common with somatic antigen of other members in the Salmonella genus.

Edwards and Bruner (1946), in their study regarding the antigenic components of *S. pullorum*, conclude the following: "The antigenic formula of *S. pullorum* is

IX, XII₁, [XII₂], XII₃. In normal cultures the XII₂ factor is variable, and forms containing a large amount or a negligible amount of XII₂ can be isolated from the same strain. It is possible for cultures to become fairly well stabilized in either form, thus giving rise to the so-called "standard" strains and "variant" or X strains. The standard strains contain only a small amount of XII₂, but the X strains contain a large amount of the antigen." Wright and Edwards (1948) emphasize that since the differentiation of standard and variant strains is based on a variational phenomenon, a diagnosis must be made with a certain degree of caution and discretion. A cursory examination of a single colony or even several colonies would permit one to conclude that the culture is predominantly in XII₂ or XII₃ form. One should examine 100 colonies or more to determine if the variant strain has become stabilized in the XII₂ form.

The typing results reported by various investigators in this country reveal that approximately 30 per cent of the strains may be of the variant type (Bivins, 1948; Heemstra, 1948; Williams *et al.*, 1949; Rhoades and Alberts, 1950; Snoeyenbos *et al.*, 1952).

Antigenic studies of pullorum and gallinarum cultures isolated in Denmark revealed that the amount of antigenic components IX, XII₂, and XII₃ was identical in 122 strains (Martfedal, 1952).

Marked antigenic stability was observed among three pullorum strains (one standard and two variant) isolated from field cases (Rhoades, 1955), whereas Luzzio *et al.* (1955) reported that the antigenic structure of *S. pullorum* may be influenced quantitatively by environmental factors.

Williams (1953a, 1953b) reported that standard, intermediate, and variant antigenic types could be differentiated with an ammonium sulfate sedimentation test. It was found that a concentration of ammonium sulfate approximating 310 gm. per liter completely cleared the supernatant fluids of standard suspensions, had little or no effect on variant suspensions,
FIG. 8.2 — (5) Colony exhibiting dentated edge, thin periphery which is markedly convoluted, striated, and tenacious. Central portion raised, dense, and faintly convoluted. Three days old. Liver infusion agar. ×10. (6) Colony exhibiting irregular outline, rough surface, opaqueness, and brittleness. Two days old. Meat extract agar. ×25. and only partially cleared intermediate suspensions. A concentration of the salt approximating 470 gm. per liter was required to clear suspensions of variant and intermediate type strains. Later, Williams and Harris (1956) observed that an ammonium sulfate concentration of 265 gm. per liter completely cleared the supernatant fluids of most *S. gallinarum* suspensions but had considerably less effect on the turbidity of suspensions of standard type cultures of *S. pullorum*. The same authors found that *S. pullorum* and *S gallinarum* antigens lacked hemagglutinating properties (Harris and Williams, 1957).

PATHOGENICITY

Pullorum infection is most prevalent among chickens. However, among the various poultry breeds, a difference in the susceptibility to *S. pullorum* may be apparent. The lighter breeds of chickens, especially the Leghorns, generally speaking, have revealed fewer reactors among tested flocks. Hutt and Scholes (1941) claim the Leghorns possess a greater genetic resistance to the disease. This view is in part also subscribed to by Roberts and Card (1935), although they state that strain differences within the various breeds must be considered. If Leghorns are to be regarded more resistant to pullorum disease on the basis of blood-testing results, then males likewise must be considered more resistant than females. Testing results for a period of years reveal a greater percentage of reactors among females than among males. This difference certainly cannot be attributed entirely to a hereditary trait existing in the male sex because the influence of environmental factors operative in a commercial plant should be recognized. From a series of investigations, Roberts and Card (1935) concluded that heredity is an important factor in resistance and susceptibility to infection with *S. pullorum*. Later Roberts et al. (1939b) reported that resistance and susceptibility of the domestic fowl to pullorum disease are related to the number

of lymphocytes. Resistant chicks revealed a higher lymphocytic count than did the susceptibles. Change in age of the chick also influenced the degree of resistance as well as the lymphocyte number. Scholes and Hutt (1942) claim that high body temperatures and resistance to *S. pullorum* are closely associated. Later Scholes (1942) concluded that resistance to *S. pullorum* more likely depends upon temperature differences than upon differences in the number of lymphocytes in the blood. While the observations reported by Hutt and Scholes (1941), Scholes (1942), Scholes and Hutt (1942), and Roberts et al. (1935, 1939b) command academic interest, from a practical viewpoint the combat against the disease through genetic selection of resistant stock does not appear as effective as the method of eliminating the disease carriers from the breeding flocks. This is substantiated by DeVolt et al. (1941) who state that the development of pullorum-resistant strains is not now a satisfactory substitute for control and eradication programs by the agglutination tests.

Clinical findings reveal that during the course of pullorum infection the levels of arginine, methionine, glycine, and tryptophan are reduced (Ross et al., 1955a). Survival time of chicks infected with the organism was increased following administration of arginine. No increase was noted when arginine was administered 48 hours prior to infection. Glycine and tryptophan had no effect on the survival time of infected chicks whereas methionine had only a slight effect (Ross et al., 1955b). Furthermore, the survival time of pullorum-infected chicks was reduced by the administration of fluoroacetate, malonate, arsenite, citrate, and succinate. Initially, greater concentrations of the organism were found in the organs of fluoroacetate-treated chicks than in the same tissues of the untreated chicks. Varying degrees of impairment of the liver tricarboxylic acid enzymes were observed when assayed during the course of the disease (Gilfillan et al., 1956a, 1956b).

While the chicken appears to be the

natural host of *S. pullorum*, other avian species also have exhibited some degree of susceptibility. Among the barnyard fowl, natural infection has been observed in turkeys (Barboni, 1937; Brunett, 1930; Dalling *et al.*, 1929; Hendrickson and Hilbert, 1930; Hewitt, 1928; and Hinshaw, 1937); ducks (Beaudette, 1938; Chute, 1962; Hinshaw and Hoffman, 1937; Letche, 1929; and Miessner, 1931); and guinea fowl (Bunyea, 1939). Natural outbreaks among pheasants (Hendrickson and Hilbert, 1931; Miessner, 1931; Van Roekel *et al.*, 1947; Williams *et al.*, 1949); quail (Emmel, 1936); sparrows (Dalling *et al.*, 1928; Reis and Nobrega, 1936); European bullfinch (*Pyrrhula europa*) (Hudson and Beaudette, 1929); and pigeons (Reis and Nobrega, 1936; van Heelsbergen, 1929) have also been reported. Canaries, goslings, turtle doves, gold finches, green finches, and bittern are reported vulnerable to infection (Villani, 1937). Edwards (1945) reported a loss of 50 birds among a flock of 75 canaries caused by a natural outbreak of pullorum disease. Thirteen birds were examined and *S. pullorum* was recovered from all of them.

At one time pullorum disease had gained a substantial foothold in commercial turkey flocks (Hinshaw, 1937, 1939). However, in recent years outstanding progress has been made in reducing the disease among turkeys, and a more detailed discussion of the disease among turkeys is presented in the section entitled "Diseases of the Turkey."

Among other fowl which were found to be susceptible either through natural avenues or through artificial means, the disease produced clinical manifestations quite similar to those observed in the chicken and turkey (Dalling *et al.*, 1928; Emmel, 1936; van Heelsbergen, 1929; Van Roekel *et al.*, 1932). Pigeons apparently are quite resistant to the organism, whereas sparrows appear to be very susceptible. The fact that sparrows and pigeons may frequently inhabit poultry plants may offer an explanation why infection appears in previously nonreacting flocks.

Upland game birds such as pheasants and quail exhibit a degree of susceptibility to the extent that game breeders must exercise preventive measures against the disease. Belding (1955) in a field survey isolated *S. pullorum* from 5 of 65 pheasants cultured. It was concluded that a significant number of wild pheasants in Michigan harbor the infection.

Guinea fowl, ducks, and geese appear quite resistant to the organism, but their role in contracting and disseminating the infection should not be considered negligible in the combat against the disease.

Among the mammalian species the rabbit is highly susceptible, as observed by Olney (1928) and Doyle (1925). Guinea pigs, mice, and cats were slightly susceptible, while rats were quite resistant (Mulsow, 1919; Rettger *et al.*, 1916). Benedict *et al.* (1941) recovered the organism from foxes and mink. Edwards and Bruner (1943) isolated a culture of porcine origin. Bruner and Moran (1949) reported the isolation of *S. pullorum* from a heifer, dog, fox, mink, and swine. In a more recent summary extending from January 1, 1957, to July 1, 1961, Moran (1961) reported that *S. pullorum* was isolated from 2 bovine and 3 mink sources. Taylor (1961) in England isolated a culture from a sheep. Human salmonellosis caused by *S. pullorum* has been reported by Edwards and Bruner (1943), Felsenfeld and Young (1944), Mitchell *et al.* (1946), Rose (1962), and Williams (1964). McCullough and Eisele (1951) produced salmonellosis with various strains of *S. pullorum* among inmates in a penal institution. Explosive onset of the illness, high fever, prostration, prompt recovery, and difficulty to recover the organism from stools were noteworthy.

MODES OF TRANSMISSION

The manner in which pullorum infection may be disseminated is of great importance from the standpoint of control, eradication, and prevention of the disease. The etiological agent may be spread through various channels (Fig. 8.3).

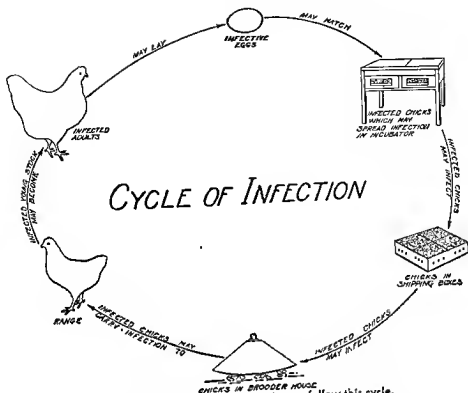
Rettger and Stoneburn (1909) isolated


FIG. 8.3 — Pullorum infection in a flock may follow this cycle.

the organism from fresh and incubated eggs which were laid by hens whose progeny succumbed to the disease. Later investigations (Dearstyne et al., 1929; Gage et al., 1914; Jones, 1913a; Rettger and Stoneburn, 1911; Runnells and Van Roekel, 1927a, 1927b; Tittsler et al., 1928) revealed that S. pullorum could be readily recovered from eggs. Runnells and Van Roekel (1927b) reported 33.7 per cent of the eggs laid by reacting hens to be infective. Jones (1913a) and Mathews (1927) reported outbreaks in adult fowls due to S. pullorum as the result of feeding incubated eggs. Van Heelsbergen (1929) emphasized that an important channel of pullorum disease dissemination is through so-called egg-picking. Rettger (1916) stated that eggs harboring large numbers of the organism produce abnormal conditions when fed to young chicks, adult fowls, young rabbits, guinea pigs, and kittens. Olney (1928) encountered a severe outbreak of

the disease among adult rabbits as a result of feeding incubated, infertile eggs. Van Roekel et al. (1932) reported that fresh eggs laid by reacting hens may produce pullorum disease when fed to noninfected hens and pullets, and it appeared that younger birds may contract the disease more readily through eating infective eggs than do older birds. They concluded that the habit of "egg-eating" or "egg-picking" in an infected flock should be regarded as a hazard to an eradication program for such a flock.

Flock conditions may increase the spread of the disease by means of the egg. Inadequate nesting facilities, which may cause birds to crowd in the nest or lay their eggs on the dropping boards and floor, result in an increase in the number of broken eggs. Pullets reaching sexual maturity frequently lay soft-shelled and hard-shelled eggs on the floor and dropping boards. The production of thin-shelled eggs may follow

outbreaks of certain diseases. All these factors are of great significance in the spread of pullorum infection in an adult flock.

The excreta of infected birds must be considered a means by which infection may spread to noninfected birds in a flock and also from one farm to another. Kerr (1930) and Van Roekel et al. (1935) have reported the recovery of the organism from the feces of hens. Van Roekel et al. (1932, 1935) observed that fecal transmission of the disease among semimature and adult stock apparently occurs very infrequently. Transmission was observed only after force feeding repeated doses of feces from infected hens. The dissemination of the disease in an adult flock by means of feces or litter contaminated with S. pullorum may be influenced by the numbers of organisms eliminated and the persistency of such elimination together with suitable environmental conditions. Such factors constitute a major problem in the eradication of the disease in a short interval retesting or multiple testing program of an infected flock. Contamination of the exterior of the egg with feces and litter containing S. pullorum and the penetration of the organism through the shell may appear plausible (Cantor and McFarlane, 1948; Stokes et al., 1956).

Furthermore, cannibalism in an infected flock may further the spread of the disease. The abdominal viscera of infected birds in many instances are heavily contaminated with S. pullorum, and when such birds are eviscerated through cannibalistic habits in a flock, they may serve as a source of infection for other birds in the flock.

The important discovery of the organism in the egg established one phase in the cycle of infection. The most frequent spread of the disease occurs from the breeding female to its progeny by way of the egg. At the present time, this is the most common mode of transmission and will continue to be the case if infected birds are tolerated in a breeding flock. It is recognized that the greater the number of infected birds in a breeding flock, the greater will be the number of infected chicks. It has also been observed that one or two infected breeding birds may be responsible for serious infection in the progeny.

Transmission of the disease in incubators through chick excretions, egg shells, and chick down has been recognized as a very serious problem in the control of the disease for many years. Hinshaw et al. (1926) definitely revealed that artificially contaminated chick down could disseminate the disease in a forced-air-draft incubator. It was emphasized that in commercial hatching, precautions should be exercised against the spread of the infection through the incubator. Bunyea and Hall (1929) pointed out that pulmonary and cardiac lesions appear to represent a form of the disease acquired by inhalation and that gross intestinal lesions, such as thickening and necrosis of the large intestine, are indicative of infection by ingestion. The significance of incubator transmission of the disease will be discussed later in this chapter.

From the time the chick is removed from the incubator to the time it is placed in a brooder, it may contract the infection through being handled or through contact with infected chicks in the same chick box. Droppings of infected chicks serve as the source of the infection. Chick boxes and any other equipment of a like nature should not be used a second time unless properly cleaned and disinfected. Chick handlers, and especially chick sexers, should give consideration toward reducing the spread of the infection when chicks from different flocks are handled.

The infection, as a rule, is spread among chicks in cohabitation during the brooding stage, especially during the first few days of age. According to Weldin and Weaver (1930), the chief source of the organism at this stage is the droppings. Mallmann (1929), through the use of a brilliant green enrichment medium, was able to isolate the organism from the feces of infected chicks. He observed that when S. pullorum was in the organs of the chicks,

it was nearly always found in the intestinal contents. Litter, feed, and water soiled with infective droppings aid in the rapid spread of the infection in a chick flock. Botts et al. (1952) reported that *S. pullorum* disappeared more rapidly from old built-up litter than in new cob litter. Gwatkin and Mitchell (1944) found that pullorum disease could be produced in chicks which had access to feed contaminated by infected flies and to the flies themselves, some of which were probably eaten by the chicks. *S. pullorum* was recovered from the feet and wings of flies at least 6 hours after exposure. The gastrointestinal tract of the flies was found to harbor the infection for at least 5 days.

The mode of spread among young chicks is often facilitated through environmental factors such as extremes in temperature, insanitary conditions, lack of or inadequate feed, and other diseases appearing concurrently. It is frequently observed that chicks which originate from a hatchery not recognized as free from pullorum infection and which are subjected to unfavorable conditions in transit will manifest greater evidence of the disease than will chicks from the same source which are subjected to more favorable conditions. Proper brooder management plays a very important role in keeping the spread of infection down to a minimum.

Pullorum infection is likely to occur regardless of the portal of entry. Van Roekel et al. (1932) report that pullorum disease can be reproduced in chickens by dropping suspensions of the organism on the conjunctiva, into an incision in the skin of the plantar surface of the foot, into the cloaca, and by oral administration. However, the oral route did not yield to the establishment of infection as readily as others that were investigated. The presence of agglutinins was detected 6 days after cloacal inoculation, 7 days in the case of ocular route, exposure in the case of cloacal inoculation, 7 days with the ocular route, 10 days each for the oral route and skin incision instillation. In some cases, agglutinins were produced but later disappeared from the blood stream. Likewise, this might occur in a naturally infected flock. Some investigators (Bunyea and Hall, 1929; Doyle and Mathews, 1928; Hinshaw et al., 1926) reported that infection may result from the entrance of the organism into the respiratory and alimentary tracts. Apparently the portal of entry for posthatching infection is more often the digestive tract than the respiratory tract.

Hence, it appears that *S. pullorum* may be eliminated and excreted from the infected host in various ways and in turn may enter the body through various avenues when suitable environment exists. This is significant from the standpoint of control, eradication, and prevention of disease.

SYMPTOMS AND LESIONS

Adult fowl. Pullorum disease in a maturing or an adult flock does not manifest the characteristics of an acute infection as a rule. The spread of infection within a flock may occur continuously, but the flock owner may not be aware of it. In contracting the infection, the bird may exhibit little or no symptomatology. Infected individuals cannot, as a rule, be detected by their physical appearance (Fig. 8.4). Experimentally infected birds have exhibited limited and transient clinical manifestations. A general depression and listlessness, accompanied by a partial or complete inappetence, may be the first symptoms following the infection. A paleness of the comb and visible mucous membranes may be observed. Diarrhea may be noted. A febrile reaction accompanied by increased thirst has been observed. Occasionally adults may succumb to artificial infection depending upon the dosage and virulency of the organism.

Natural epornitics in a flock have been observed. Jones (1913a) reported a natural outbreak among adult fowl which was attributed to the feeding of eggs discarded from an incubator. Evidence of disease was observed 16 days after the feeding of the infective eggs, and during a period of 6 weeks a loss of 50 birds among a flock of 700 hens was sustained. The

(Storrs Agr. Exper Sta)

symptoms noted were paleness of the comb and mucous membranes; scaly, shrunken, and grayish appearance of the comb; listlessness; progressive depression; droopy wings, retraction of head and neck; inappetence; and usually diarrhea. The duration of the incubation period was from 16 days to 3 weeks. The course of the disease sometimes terminated fatally in 24 hours, usually continued 4 or 5 days, and occasionally even longer. A definite leukocytosis was observed.

Plastridge and Rettger (1930) have observed among adult flocks acute outbreaks of the disease caused by a highly pleomorphic type of *Salmonella pullorum*. Acute flock infections should not be mistaken for outbreaks of fowl typhoid, fowl cholera, avian listerellosis, and avian monocytosis.

Among birds dying from acute infection, Jones (1913a) observed marked emaciation; enlarged and distorted heart due to grayish-white nodules; enlarged, yellowish-green and granular liver coated with fibrinous exudate; friable spleen of normal size with focal necrosis; minute necrotic foci of the pancreas; enlarged kidneys with parenchymatous degeneration; injection of mesenteric vessels; and a fibrinous exudate coating the abdominal viscera.

The lesions found in the more common chronic carrier are the misshapen, discolored, cystic ova (Fig. 8.5), and frequently an acute or chronic pericarditis. The diseased ova usually contain oily and cheesy materials enclosed in a thickened isocapsule. The organism can be readily isolated from the ovarian cysts. These cysts may be closely attached to the ovary, but frequently they are pedunculated and may become detached from the ovarian mass. In such cases they become embedded in the adipose tissue of the abdominal cavity. In one case a pedunculated ovum was recovered as a foreign body from a normal-appearing egg (Fig. 8.6). Ovarian and oviduct dysfunction may lead to abnormal ovulation or oviduct impaction, which in turn may bring about extensive peritonitis

and adhesions of the abdominal viscera (Fig. 8.7). Advanced lesions of this type seldom, if ever, fail to yield *S. pullorum* on culture.

Lesions less extensive in nature may involve the heart. Quite frequently pericarditis is observed both among females and males. The changes that have occurred in the pericardium, epicardium, and pericardial fluid appear to be dependent on the age of the disease process. In some cases the pericardium exhibits only a slight translucency, and the pericardial fluid may be increased and possess a turbidity. In the more progressive stages the pericardial sac is thickened and opaque and the pericardial fluid is greatly increased in amount, containing considerable exudative material. This may be followed by permanent thickening of the pericardium and epicardium and partial obliteration of the pericardial cavity by adhesions (Fig. 8.8). The organism can usually be recovered from such a process.

In the male the infection is frequently found in the reproductive organs. Edwards and Hull (1929) reported the localization of the organism in the testicle and vas deferens. A thickening of the tunica albuginea and complete obliteration of the seminiferous tubules were observed. The testis revealed multiple small abscesses and areas of round cell infiltration. There was no evidence of spermatogenesis. The lumen of the vas deferens was enlarged and filled with a dense structureless homogeneous exudate. Other cases of infection in the male reproductive system have been reported (Fig. 8.9). Pericarditis is frequently observed among infected males, and less frequently small infective cysts containing amber-colored, cheesy material may be found embedded in the abdominal fat or attached to the gizzard or intestines.

Bushnell *et al.* (1926) reported the isolation of the organism from abscesses on the skin and the legs. Subcutaneous abscesses over the sternal region and cystic enlarged thyroids have yielded the organism. Gwatkin and Glover (1930) isolated

FIG. 8.7 — Impacted oviduct removed from an infected hen. Parts I and II are the funnel and albumen secreting portions, respectively. Part III is the shell gland portion. Adhesions of the serosa.

the organism from the nasal passages of 2 among 61 adult birds examined. Beach and Freeborn (1927) reported the isolation of *S. pullorum* from the middle ear with no evidence of infection in any other part of the body. Gwatkin (1946) recovered the organism from the thymus glands.

Chick. Manifestations of pullorum disease were first recognized among young chicks, and the malady may be considered as principally a chick disease. The symptoms exhibited by an infected brood of chicks are not specific for pullorum disease, although in many cases a tentative diagnosis based on clinical evidence has been substantiated by the isolation of the etiological agent.

In a typical outbreak of infection among chicks, the following symptoms may be observed: The onset of the disease varies with the degree, virulence, and source of the infection, and with the management given the chicks. If chicks are hatched from infective eggs, moribund and dead chicks may be observed in the incubator or within a short time after hatching. The chicks manifest a somnolence, weakness, and loss of appetite, and death may follow

FIG. 8.8 — (Left) Normal heart. (Right) Infected heart exhibiting pericarditis and epicarditis.

FIG. 8.9 — Testicles removed from a reacting adult male. Testis I—atrophic and very firm; S. pullorum reisolated. Testis II—normal in size and texture; S. pullorum not isolated.
FIG. 8.10 — Nine-day-old, naturally infected pullorum disease chicks. S. pullorum was isolated from chicks II and III. Chick III died two days after it was photographed.

suddenly. In some instances, evidence of the disease is not observed until several days (5 to 10) after hatching. The disease gains momentum during the following 7 or 10 days. The peak of the infection usually occurs during the second or third week of chickhood. In such instances, the chicks exhibit a lassitude, an inclination to huddle together under the hover, loss of appetite, an accumulation of urinary and alimentary excretions in and around the vent, drooping of the wings, somnolence, and a distorted body appearance (Fig. 8.10). Frequently one may detect a shrill cry from a chick when voiding excreta. This is particularly true among those chicks that have an accumulation of whitish, chalklike excreta, stained greenish brown, in and around the vent.

Jungherr (1935) reports that affected chicks manifest a febrile reaction as indicated by the increased temperature of the legs. He also mentions that affected chicks may appear as having been "dipped in water" which he explained as probably brought on by a water-logged condition of the body muscles which permits the excess fluid to ooze through the skin. Hutyra et al. (1938) claim that a febrile condition is responsible for the increased renal activity and elimination of the whitish material adhering to the vent and adjacent parts.

Labored breathing may be observed even to the extent that chicks may be gasping for breath. This should not be confused with what is commonly designated "brooder pneumonia" or mold infection, and neither should it be mistaken for infectious bronchitis, Newcastle disease, or some other respiratory disturbance. The mortality may vary from no losses to approximately 100 per cent in serious outbreaks. The morbidity and mortality rates are dependent upon many factors. The greatest losses occur usually during the second week after hatching with a rapid decline during the third and fourth weeks. Survivors may be greatly retarded in their growth and appear as underdeveloped and poorly feathered birds (Fig. 8.11). However, some survivors may not reveal any great setback in growth, but grow to maturity even though harboring the infection. Chick flocks which have passed through a serious outbreak usually reveal a high percentage of carriers at maturity.

Evans et al. (1955) reported a blindness in chicks associated with salmonellosis. In one case S. pullorum was isolated from the anterior chamber of the eye and from the tibiotarsal joint. Fluctuating swellings of the tibiotarsal and the humeroradial and ulnar articulations, containing amber viscous exudate or a lemon-colored gelatinous material, have been ascribed to S. pullorum infection in chicks 2 weeks or older. Bacteriologic examination of the inflammatory process will yield pure cul-

tures of the organism. This arthritic involvement has been observed by several workers (Beaudette, 1936; Ferguson et al., 1961; Van Roekel and Smyser, 1962). Davis et al. (1961) referred to this clinical manifestation as a subcutaneous blisterlike lesion. One should not confuse this manifestation of pullorum disease with arthritic conditions produced by other infectious diseases.

Chicks hatched from an infected flock and raised on the same premises will usually reveal less mortality from the disease than chicks from the same flock shipped away.

In chicks that die suddenly in the early stages of brooding, the lesions are limited. The liver is enlarged and congested, and the normal yellow color may be streaked with hemorrhages. In the septicemic form, an active hyperemia may be found in other organs. The yolk sac and its contents reveal slight or no alteration. In the more protracted cases, an interference with yolk absorption may occur, and the yolk sac contents may be yellowish in color and of creamy and cheesy consistency. Necrotic foci or nodules may be present in the cardiac muscle (Fig. 8.12), liver, lungs (Fig. 8.13), ceca, large intestine, and the muscle of the gizzard. Pericarditis may be observed in certain instances. The liver may reveal punctiform hemorrhages and focal necrosis The spleen may be enlarged (Fig. 8.14) and the kidneys congested or anemic with ureters prominently distended with urates. The ceca may contain a cheesy core, sometimes tinted with blood, which should not be confused with a somewhat similar lesion encountered in coccidiosis The wall of the large intestine may be definitely thickened Frequently peritonitis is manifested. Doyle and Mathews (1928) report that the liver is the most constant seat of gross lesions and followed in order by the lungs, heart, gizzard, and ceca. Among chicks only a few days old, the lung lesions may consist only of a hemorrhagic pneumonia, whereas in older chicks small yellowish-gray nodules and areas of gray hepatization may be found.

FIG. 8.14—(A) Normal spleen (17-day-old chick). (B) Pullorum-infected spleen exhibiting marked enlargement (16-day-old chick).

The nodules in the myocardium may attain a size causing a marked distortion in the shape of the heart.

The histopathologic findings in young chicks affected with pullorum disease present features not markedly different from those in other infectious diseases. Doyle and Mathews (1928) state that in young chicks the livers show hyperemia, hemorrhages, focal degeneration, and necrosis (Fig. 8.15). They claim that the accumulation of endothelial leukocytes which replace the degenerated or necrotic liver cells is a characteristic cell reaction of the liver to S. pullorum infection. The histopathologic pulmonary lesions may consist of diffuse, acute congestion and hemorrhage in the early stages. Later, well-defined focal lesions appear which consist chiefly of a mononuclear infiltrating type of cell, serofibrinous exudate, and cellular debris. The larger lesions may involve several lobules, bronchioles, and bronchi terminating in necrosis.

The nodules in the myocardium and in the muscle of the gizzard represent largely an infiltration with mononuclear cells and degenerative changes of the muscle fibers.

The pulmonary and cardiac lesions may be considered of considerable diagnostic importance. However, for an accurate diagnosis of diseased specimens, the presence or absence of these findings should be confirmed by bacteriologic examination.

DIAGNOSIS

The identification of pullorum disease in maturing and adult stock should be made on the basis of serologic findings and

FIG. 8.15 — Liver revealing focal degeneration and necrosis, ×100.
not on clinical and postmortem observations. Bacteriologic examination should be made in acute cases of the disease and in certain instances when the serologic findings may appear questionable. Other infectious diseases such as fowl typhoid, fowl cholera, paratyphoid infection, and avian monocytosis may at times be difficult to differentiate from pullorum infection without recourse to a bacteriologic examination. Disturbances of the female reproductive system are common in chickens, but pullorum disease can be incriminated for only a portion of them (Fig. 8.16). Serologic findings should not be considered final for all suspicious cases of pullorum disease. Fowl typhoid-infected birds and occasionally those harboring paratyphoid organisms will give a positive test when their sera are tested with pullorum antigen. Furthermore, it has been observed in routine pullorum testing that other bacterial organisms may cause birds to produce sera that will give nonspecific reactions with pullorum antigen (Garrard et al., 1947; Gwatkin, 1946). Nonspecific agglutination reactions for pullorum disease were observed with serum obtained from chickens infected with *S. enteritidis* var. *danysz*, an organism used in rat poison (de Blieck and Marthedal, 1952). Bacteriologic examination should be supplemented in such instances for an accurate diagnosis.

The diagnosis of the disease in young chicks should be based on bacteriologic examination even though well-pronounced lesions which may be considered quite characteristic of the infection are observed. Such a diagnostic procedure should definitely determine the presence or absence of fowl typhoid, paratyphoid, staphylococcosis, coccidiosis, infectious bronchitis, aspergillosis, and noninfectious diseases.

Standard Methods of Diagnosis of Pullorum Disease in Barnyard Fowl (Anon., 1933) adopted by the Conference of Official State and Federal Research Workers in Animal Diseases of America in 1931 and by the United States Livestock Sanitary Association in 1932 state that "the only criterion of infection with *Salmonella pullorum* shall be the isolation of this organism from the blood and body tissues of suspected chicks and its complete identification." Ordinary standard beef infusion agar is recommended for the isolation of the organism, and in case chicks have been in transit for some time, leading to partial decomposition of the specimens, brilliant green liver infusion medium as described by Mallmann (1929) is recommended. Various enrichment and selective media (tetrathionate broth, selenite broth, S-S,
FIG. 8,16 — Cystic ovary infected with *Escherichia coli*.

and MacConkey agar) have been found useful in isolating the organism.

Cultures should be incubated from 21 to 48 hours at 37°C., and characteristic colonies should be identified by Gram-stained slide mounts and by their fermentative reaction in glucose, lactose, saccharose, and dulcitol. The antigenic specificity should be tested against known positive and negative pullorum sera. A Gram-negative medium rod, producing acid and gas, or acid in only glucose, and agglutinating with positive serum, is to be regarded as a typical criterion for *Salmonella pullorum*. The antigenic specificity may be tested with the rapid serum method, as recommended by Stafseth and Corbutt (1940), which may expedite completion of the examination and reporting the diagnosis to the consignee. Approximately 48 to 96 hours are required to obtain a diagnosis after the consignment arrives at the laboratory. Reliable and expeditious diagnostic service is essential because it may avoid serious losses and spread of the disease.

THERAPEUTICS

Until recently, efforts to reduce losses in outbreaks of pullorum disease through medicinal treatment have met with little or no success. Drugs and chemicals have been reported to have no beneficial influence when taken into the alimentary tract (Beach and Freeborn, 1927). Hypochlorite solutions were found to be of some value as a drinking water disinfectant. However, from a practical standpoint, considering the various other channels through which the organism may spread in a flock, it appears doubtful whether the expenditure for a drinking water disinfectant would be justified.

Introduction of sulfonamides in the control of the infection has revealed that sulfamerazine, sulfamethazine, and sulfaquinoxaline may be effective in reducing mortality from the disease. However, these drugs failed to prevent a retardation in growth associated with the disease. Likewise, the incidence of reactors among survivors was not reduced by administration of these drugs (Severens et al., 1945; Bottorff and Kiser, 1916; Gwatkin, 1946; Anderson et al., 1918; Cole, 1948; Dickinson and Stoddard, 1919; Grumbles et al., 1950; Cooper et al., 1951). The value of antibiotics in the control of pullorum disease is not known. Chang and Stafseth (1950a, 1950b) found that streptomycin was bactericidal and that this activity was enhanced by the use of sulfadiazine. Recently furazolidone, commonly known as nf-180, has been found to have some merit in preventing serious losses from the disease. The drug is administered in the feed at levels of .011 per cent and higher (Bierer, 1961; Gordon and Tucker, 1955; Henderson et al., 1958; Richey, 1962; Smith, 1951; Wilson, 1955, 1956; Smyser and Van Roekel, 1957, 1958).

The use of sanitary drinking fountains and feed hoppers, the frequent removal of contaminated litter, the maintenance of proper and uniform brooding temperatures, the avoidance of overcrowding, and the prompt removal of visibly sick and dead chicks are management measures which will reduce the spread of the infection and minimize losses.

Moore et al. (1934) have shown that increasing the brooder temperature from 5

to 10 degrees above that recommended for normal brooding operations will reduce the mortality. Bushnell *et al.* (1926) concluded that the feeding of sour milk is of little value in the control of pullorum infection, except that it may increase the vigor of the chicks due to its food value. Roberts *et al.* (1939a) reported that diet exerted an influence on the morbidity and mortality due to *S. pullorum*. A high mortality resulted from the feeding of laying mash, but when chick mash was substituted the high mortality disappeared.

Biotherapy (vaccines, bacterins, and serums) (van Heelsbergen, 1929) has been tried but has not given satisfactory results. According to Mallmann (1931a), phage therapy also has been ineffective in controlling the disease.

Incubator sanitation and disinfection are very essential in combating pullorum disease. At the start of hatching operations and repeated between hatches for the duration of the hatching season, incubators should be thoroughly cleaned and disinfected. Hatcherymen frequently overlook the fact that thorough cleaning ought always to precede disinfection. Liquid disinfectants and fumigants have their effectiveness greatly reduced if used in incubators containing chick down, eggshells, excreta, and other debris.

Formaldehyde, an extensively used fumigant, has been found very effective in incubator disinfection. Investigations (Bushnell *et al.*, 1929; Bushnell and Payne, 1931; Graham, 1941; Gwatkin, 1927; Insko *et al.*, 1941) have revealed that definite procedures must be followed to obtain the optimum results. It is generally recommended that 35 cc. of formalin be added to 17.5 gm. of potassium permanganate to fumigate 100 cubic feet of incubator space with wet-bulb and dry-bulb temperature readings of 86°–90° F. and 100° F., respectively. The exposure to the gas should be not less than 1 hour nor more than 3 hours.

Burton (1946) emphasizes that at least 150 cc. of formalin and 100 gm. of potassium permanganate be used to fumigate 100 cubic feet of inside incubator space. After 20 minutes' exposure to the gas, complete destruction of *S. pullorum* was observed. It is stressed that factors such as air leakage, improper humidity and temperature, circulation of gas within the incubator, and duration time of fumigation all play a very important role in effective fumigation of the incubator. Considerable leakage of gas was found in some commercial machines. Earlier Graham (1941) reported that maximum results of fumigation (using 35 cc. of formalin and 17.5 gm. of potassium permanganate for each 100 cubic feet) may be expected only if incubators are relatively clean and if the doors of forced-draft incubators are kept closed for a minimum of 3 hours following the release of the formaldehyde. The gas may then be liberated from the machine either by opening the doors for a few minutes or by neutralizing with strong ammonia water. The ammonia water may be sprinkled on the walls of the inside chamber. In forced-draft incubators, the diffusion of gases is very rapid and effective; however, first the proper temperature and humidity should be established. Insko *et al.* (1941) advise raising the wet-bulb reading to 92°–94° F. at the time of fumigation and maintaining the dry-bulb thermometer at normal operating temperature. Fumigation at high concentrations during the first 3 days of incubation is advised against, because the embryos at this period can tolerate less formaldehyde than at a later age. Losses of practical significance were not observed until four times normal concentration (35 cc. formalin per 100 cubic feet of space) of the fumigant was used.

When eggs are hatched in separate hatching compartments, they should be fumigated on the eighteenth to twentieth day of incubation. Fumigation may be repeated at short intervals during the hatching process but should not be delayed until after the chicks have dried. The relative humidity should be maintained at a high level, which will aid the chick in withstanding the gas. The incubator should

remain closed for 8 to 10 minutes. Immediately after each fumigation all chicks, whether wet or dry, should be removed from the incubator and kept in a comfortable environment. Ammonium hydroxide may be used to advantage in neutralizing the formaldehyde and in facilitating the handling of the chicks.

In addition to the formalin and potassium permanganate method, the use of cheesecloth saturated with formalin has been recommended. This latter method may be more economical in the use of formalin, but it requires a longer fumigation period. Commercial fumigants (Graham, 1941) are also available on the market, but the public should refrain from using such preparations until they are endorsed by qualified authorities.

Effective incubator fumigation by the formaldehyde method cannot be expected unless proper conditions prevail, and even then certain limitations exist as in the case of fumigating chicks in the process of hatching Complete destruction of S.

pullorum does not occur, but it is possible to reduce the chances of infection to some degree within the incubator. Incubator fumigation should be regarded as only one step or means that may be employed to advantage in a program designed for the control, eradication, and prevention of the disease.

CONTROL AND ERADICATION

Rettger *et al.* (1914) first reported that they had definitely established the complete cycle of infection and that chicks which were infected with the organism when small may develop into permanent carriers and be a constant source of danger to young and old stock. They found that the carrier condition might be established in approximately 25 per cent of an infected flock. To combat the disease successfully, these investigators stated that the infection cycle should be broken. Attempts were made to detect the carriers in flocks by the recognition of diseased ovaries in birds that were slaughtered for meat. This

FIG. 8.17 — Macroscopic tube agglutination test. (Left), Negative reaction. (Right), Positive reaction

method was found inadequate and impractical in eliminating all infected birds from the flock.

A later method, the bacteriologic examination of fresh eggs from an infected flock, was also found impractical, unreliable, and costly in the eradication of disease.

Jones (1913b) reported the use of the macroscopic tube agglutination test as a means of detecting carriers of the infection and recommended the lower serum dilutions (1:50, 1:100, and 1:200) for routine testing (Fig. 8.17). The test was considered to be valuable in detecting infected fowl, but its practicability was dependent upon the value of the breeding flock.

The important contribution by Jones must be regarded as the foundation work for the diagnostic procedures which are in use at the present. Gage et al. (1914), and Rettger et al. (1915) substantiated the results of Jones and later employed the test in statewide campaigns with the objective of detecting flocks free from the disease as well as eliminating the disease by the detection and removal of the reactors.

In 1914 Rettger et al. (1915) tested 107 flocks representing 14,617 birds which revealed 9.85 per cent reactors. Among 786 males tested only 2.9 per cent reacted. As to range of infection in terms of percentage, the tested flocks were classified as follows: 0 per cent, 28; 1–10 per cent, 34; 11–20 per cent, 18; 21–30 per cent, 10; 31–40 per cent, 10; 41–50 per cent, 4; 50+ per cent, 3. The White Leghorn flocks revealed a lower positive flock incidence than did the heavier breeds (57.1 per cent White Leghorns, 84.6 per cent Barred Rocks, and 88.4 per cent Rhode Island Reds).

The results obtained from the practical application of the macroscopic tube agglutination method revealed that a single test is not sufficient, as a rule, for the complete elimination of infected birds from a flock. However, improvement in hatchability and livability was observed among eggs and chicks, respectively, produced by

tested flocks. It was recommended that only nonreacting birds be used for breeding purposes.

The initial testing of flocks in Massachusetts revealed results comparable to those reported in Connecticut. It is of interest to note that pullorum disease-free flocks did exist, while other flocks might reveal a large percentage of reactors.

As the testing programs expanded and additional states adopted the routine testing of flocks, the test itself was gradually modified and improved as to its technique. Various investigators, organizations, and federal and state agencies have contributed to the serologic diagnostic methods employed at the present time. The National Poultry and Turkey Improvement Plans (1963) endorse three methods [(1) The Standard Tube Agglutination Test; (2) The Stained-Antigen, Rapid Whole-Blood Test; and (3) The Rapid Serum Test] for official testing. The choice of method is determined by many factors and objectives peculiar to a state or a region. In some states the macroscopic tube agglutination method is considered the only official method for testing of flocks. In other states the rapid serum method and the tube test are regarded as official. In many states all three methods may be employed, but the whole-blood test is the one most generally used.

The techniques and procedures for the three official methods are described in detail by the Animal Husbandry Research Division, Agricultural Research Service, United States Department of Agriculture, Washington, D.C. (The National Poultry and Turkey Improvement Plans 1963). A brief review of each method is as follows:

THE STANDARD TUBE AGGLUTINATION TEST

The blood samples shall be collected by a properly qualified and authorized person. Suitable blood tubes, shipping containers, and bleeding and leg-banding equipment should be furnished by the diagnostic laboratory or the authorized agency in

FIG. 8.18 — Collecting blood samples for laboratory test.

FIG. 8 19 — Incising the median vein of the wing (Vena cutanea ulnaris).

FIG. 8.20 — Collecting the blood into a numbered etched tube.

charge of the testing program (Fig. 8.18). Blood tubes should be thoroughly cleaned and heated in a hot-air sterilizing oven. Cork stoppers should be boiled or washed and dried in a hot-air drying oven. Shipping containers for the blood samples should be constructed to permit washing and disinfection.

All birds tested are to be officially leg banded. The blood tube is identified with the leg-band number which is inscribed on the etched portion of the tube or on a gummed label. A small amount of blood (½ to 2 cc.) is collected from the median vein of the wing (Vena cutanea ulnaris) by incising the latter with a sharp-pointed lancet or knife (Figs. 8.19 and 8.20). The tube is laid on its side, permitting the blood to clot in a long slant. After the blood has coagulated, the samples are packed in containers designed for shipment by mail, express service, or special messenger to the laboratory. In extremes of temperature, precautions should be taken against freezing or overheating because the blood samples should arrive at the laboratory in a fresh state and unhemolyzed condition for a satisfactory test. All hemolyzed or spoiled samples should

be rejected. The diagnostic laboratory should be equipped with proper and adequate refrigeration facilities where blood samples should be retained until the sera have been tested and results of the tests are known. Occasionally, a retest on the same serum may be necessary to determine the pullorum status of a bird.

The antigen for the tube test should be prepared from representative strains of S. pullorum which are known to contain the different antigenic components normally found in S. pullorum (Edwards and Bruner, 1916). Furthermore, the strains should possess high agglutinability with positive serum but should not agglutinate with negative or nonspecific sera. The following pullorum strains are widely used for the official tube test antigen with satisfactory results: strain 17 isolated in 1916; strain 19 isolated in 1911; strain 20 isolated in 1917. All strains are of the "standard" type and were originally isolated by Doctor Leo F. Rettger (Williams and MacDonald, 1955). Stock cultures of the antigen strains should be grown and maintained on nutrient agar medium composed of dry granular agar (Difco) 2.0 per cent, Bacto peptone (Difco) 1.0 per cent, beef extract

(Difco) 0.4 per cent, and water. The final hydrogen-ion concentration should range from 7.0 to 7.2. The cultures should be transferred not more than once a month. Seed cultures should be taken from the stock strains rather than from rapid serial transfers in order to avoid contaminants or possible variation in the characteristics of the organism. Large test tubes, Kolle flasks, or Blake bottles containing nutrient agar medium may be used for producing the antigen. After 48 to 72 hours' incubation, the growth is washed off with sufficient phenolized (0.5 per cent) saline (0.85 per cent) solution to produce a very concentrated suspension. This suspension is filtered through sterile absorbent cotton or glass wool into sterile glass-stoppered bottles. The washings for each of the three strains are combined in equal volume-density, and the stock antigen is stored at 8°–10° C.

An alternate medium, designated thiosulfate glycerin and frequently referred to as TG medium, may be used to prepare antigen. It is claimed that this medium provides an antigen of excellent specificity and greatly increases the yield of the antigen from a given volume of medium (Williams and MacDonald, 1955).

For routine testing, a dilute antigen is prepared from the stock antigen by diluting the latter with physiological saline solution containing 0.25 to 0.5 per cent phenol. The turbidity of the antigen corresponds to 0.75–1.00 on the McFarland nephelometer scale, and the hydrogen-ion concentration is adjusted to pH 8.2–8.5 by the addition of dilute sodium hydroxide. The dilute antigen is prepared each day in order to reduce dissolution and plasmolysis to a minimum at the specified hydrogen-ion concentration.

The amount of diluted antigen employed in individual tests may vary from 1 to 2 cc.; however, the amounts should be constant and placed in clean, clear test tubes. Commercial devices are recommended for this phase of the work. The sera are added to the test tubes containing the antigen with a serologic pipette or a serum-delivery device which is accurately calibrated to deliver definite amounts. The maximum dilution employed must not exceed 1:50 and, according to available data, the 1:25 dilution appears to be the most efficient. After the serum and antigen are well agitated, the mixture should be incubated for at least 20 hours at 37° C.

The results of the tests are interpreted as follows: *Negative test* represents a test in which the fluid remains uniformly turbid. *Positive test* represents a test in which the antigen reveals a distinct clumping, and clumps of cells have settled to the base of the tube with the supernatant fluid being clear. Gradation of clumping or agglutination may occur between negative and complete positive tests. These may be designated as slightly and strongly suspicious.

All suspicious and positive reacting tests should be reported to the agency responsible for the disposition of infected birds. Also, all broken, missing, and spoiled samples should be reported. In case the past status of the flock has been free of infection and only a few reactors are detected, the serologic diagnosis should be confirmed by bacteriologic examination of the reactors. An approved bacteriologic examination procedure for reacting birds has been prescribed for official testing (The National Poultry and Turkey Improvement Plans, 1963). Such a procedure will avoid a false diagnosis of fowl typhoid or paratyphoid infections. If only suspicious reactions are observed in a flock, then the strongest reacting birds should be submitted to the laboratory for retesting and a careful bacteriologic examination. In routine testing, flocks should not be condemned as infected on the basis of doubtful or atypical reactions because such reactions may be due to causes aside from *S. pullorum*. If no conclusive evidence of pullorum infection can be found, the flock should be regarded as negative. This statement is based on observations made in routine testing in the New England States (Van Roekel and Bullis, 1937). The lowering or removing of the official pullorum

status of a flock should be exercised only after conclusive evidence of infection has been established.

THE STAINED-ANTIGEN, RAPID WHOLE-BLOOD TEST

The stained-antigen, rapid whole-blood test was first developed by Schaffer et al. (1931), and Coburn and Stafseth (1931). At the present time, the antigen for this method is produced under federal license from the Secretary of Agriculture, in accordance with specific directions.

For a detailed description of the official procedure, reference should be made to the revised report on The National Poultry and Turkey Improvement Plans (1963). Briefly, the method may be described as follows: A wire loop, three-sixteenths of an inch in diameter made on the end of a 2½-inch length, noncorrosive wire (Brown and Sharpe gauge No. 24), is used to measure the blood. One end of the wire is inserted into a cork stopper which serves as a handle. A loopful of blood is taken from the punctured wing vein and contains approximately .02 cc. when the blood appears to bulge out. The loopful of blood is mixed with the stained antigen which has been placed on

a glass plate marked off in inch squares. The antigen is measured with a medicine dropper whose tip is constructed to deliver .05 cc. when held in a vertical position. An antigen-blood dilution of two to one or three to one has been reported to give the most satisfactory results. The loopful of blood is mixed with the antigen, and the mixture is spread out about an inch in diameter. The loop is washed in clean water and dried with cheesecloth or blotting paper. The glass plate is tilted up and down several times to aid in the mixing of the blood and antigen and apparently has some influence on the speed of the agglutination. Reactions may occur within a few seconds up to 2 minutes. Delayed reactions should be regarded as nonspecific. A positive reaction consists of the clumping of the violet-stained cells floating in clear fluid (Fig. 8.21). The rapidity of the reaction and the size of the clumps are influenced by the agglutinating power of the blood. Partial reactions should be regarded as suspicious and treated in the same manner as those observed in the other testing methods. Sometimes a very fine granulation appears which should be considered negative. Very infrequently agglutination of the red blood cells occurs and should not be confused with the
FIG. 8.21 — Stained-antigen, whole-blood test. (Left) Negative reaction. (Right) Positive reaction.

clumping of the stained bacterial cells. The fine marginal flocculation, which may be observed before drying of the mixture, is to be considered negative. A negative *reaction is one in which the mixture remains homogeneous for at least 2 minutes.* MacDonald (1917) developed a colloidal-sulfur medium (K) for the production of antigen. This medium produces an antigen which is superior to other stained antigens provided previously. Since July 1, 1953, all whole-blood crystal violet–stained antigen has been produced according to the K formula and is known as K antigen (Williams and MacDonald, 1955). Since July 1, 1957, all antigens have been of the polyvalent type which contains both "standard" and "variant" type strains (The National Poultry and Turkey Improvement Plans, 1963).

Only those reactions which appear within 1 minute after the mixing of the blood and antigen should be considered definitely positive, while reactions delayed for 2 minutes should be considered suspicious.

In order to approach uniformity of results, the testing plate should be well lighted at all times, and the temperature should remain at a constant level. A temperature of 75°–85° F. is considered satisfactory. The test plate should be free of dust and so constructed that it can be tilted with ease. The tested birds can be retained in either special holding equipment or crates and released as rapidly as the results of the test become known (Fig. 8.22). All birds in the tested flock should be officially leg banded. The accuracy of the results is greatly influenced by the competency of the testing agent and his thoroughness and care in conducting the test.

THE RAPID SERUM TEST

The rapid serum test for the detection of pullorum disease carriers was developed by Runnells *et al.* (1927). The blood samples may be collected in a manner similar to that described for the tube test. The antigen employed should consist of representative strains of *S. pullorum* which are of known antigenic composition and high agglutinability, but which are not

FIG. 8.22 – Conducting the stained-antigen, whole-blood test in the poultry house.

sensitive to negative and nonspecific sera. The strains are suspended in 12 per cent sodium chloride solution containing 0.5 per cent phenol. The turbidity is adjusted to 50 times greater than tube 0.75 of McFarland's nephelometer.

A box with a glass top ruled off in inch squares and improvised with lighting and heating facilities was used for testing. Two serum-antigen dilutions corresponding to the 1:50 and 1:100 dilutions for the tube test were employed. The amounts of serum used were 0.02 cc. and 0.01 cc. to which was added 0.02 cc. of antigen. The serum and antigen were mixed thoroughly with a toothpick. Positive reactions may occur quickly, but delayed reactions may require several minutes (Fig. 8.23). Gradations of reactions occur in this method as in other methods. Considerable experience is necessary for proper interpretation. This method should be used only in competent hands if the results are to be regarded as official. The results of the tests and the numbers of spoiled, broken, and missing samples should be reported directly to the flock owner or the agency in charge of the field work.

MISCELLANEOUS TESTS

Other tests, including the intradermal, precipitin, and complement-fixation methods, were found to be unreliable and impractical for the control and eradication

of the disease (Ward and Gallagher, 1917; Bushnell and Brandly, 1929; Edwards and Hull, 1929; Michael and Beach, 1929; and Rettger et al., 1930).

Williams (1951) has described a so-called spot test for the detection of infected chickens. This test may serve as a useful adjunct to the agglutination test, especially in flocks in which suspicious reactors are detected.

Limited observations have been reported concerning a flocculation test for pullorum disease by Roznowski and Foltz (1958).

In the control and eradication of the disease, the actual detection of infected birds through testing is only an integral part of a large program. A testing program which does not consider all the ramifications of pullorum disease is doomed to meet failure. Indiscriminate testing for the purpose of advertising or promoting the sale of stock should be prohibited. An adequate testing program should give consideration to the following eradication and preventive measures:

1. All birds over five months of age should be tested annually in order to determine the true status of a flock. When infection exists in the flock, partial flock testing is not as effective in eliminating the disease from the premises as is 100 per cent testing.

On commercial farms where large units of birds are maintained for egg production
FIG. 8.23 — The rapid serum agglutination test. (Left) Negative reaction. (Right) Positive reaction.

in addition to units held for breeding purposes, the testing of only the breeding stock might suffice provided proper facilities exist for the segregation of the two groups and adequate precautionary measures are carried out against direct or indirect contact between the two groups. One should not consider a plant having both untested and tested birds as safe as a plant with only tested birds. A keen and careful buyer of stock will always carefully investigate this point and buy only from a flock whose status is without doubt.

Intermittent testing, that is, testing one year and not the next, or on alternate years, is a procedure which is not effective in establishing or maintaining a free flock. Those engaged in an official testing program should adopt the policy of minimizing such a practice.

2. Flocks revealing infection should be retested within two or four weeks until a negative report is obtained provided the value of the birds justified the expenditure. In the majority of cases, infection can be eliminated from a flock through short interval testing. Two or three retests in many instances are sufficient to detect all the infected birds in a flock (Table 8.1). Occasionally, infection may be very persistent, so that its elimination may not be accomplished by a testing program.

A retesting program for an infected flock or flocks should be complete to the extent that all infected birds have been detected and removed. Permitting one or a few infected birds to remain in a flock after a partial retesting program has been applied may lead to the propagation of the infection in the progeny of that flock which will necessitate a program of multiple testing from year to year to combat the disease. The objective should be to eliminate all of the infected birds from the breeding flock and reduce the cost of testing to one annual test in order to determine the status of the flock. In areas where the majority of flocks are free of the disease, the need for multiple retesting has been eliminated, which consequently represents a great economy to the poultry industry.

Infected flocks of inferior breeding or revealing heavy infection should not be considered for retesting. Replacements from known pullorum-clean sources will prove more effective and less expensive than intensive retesting for the establishment of a free flock. However, the pullorum disease-free stock selected for replacements should be protected against reinfection, which is not always fully appreciated. In some states the policy of replacement of infected flocks with stock from free sources has contributed more to the eradication of the disease and at less cost than could have been accomplished through retesting. In areas where an appreciable number of flocks still harbor the infection, it would behoove the official state agencies, commercial hatcherymen, and flock owners to carefully consider ways and means whereby similar progress can be made in their respective localities. Once the goal of pullorum freedom has been attained, a retrogression to pullorum-infected flocks will not be tolerated.

3. Every reactor, regardless of its value, should be removed from the premises and sold for slaughter immediately upon the completion of the test. When reacting birds are submitted to the laboratory for necropsy to confirm the results of the test, the recommended minimum procedure for bacteriologic examination should be followed (The National Poultry and Turkey Improvement Plans, 1963). Reactors should not be retained or sold for egg production because they would serve as sources for the spread of the disease.

4. The poultry houses, runs, and equipment should be thoroughly cleaned and disinfected immediately after removal of reactors. Disinfectants approved by federal or state agencies are recommended. Thorough cleaning of pens and other contaminated areas on the premises is most essential to attain eradication. Van Roekel et al. (1941) have observed that S. pul-

lorum may remain viable on a dry cloth maintained at room temperature for at least 7 years and 8 months. Allen and Jacob (1930) found the organism to persist in a virulent condition for at least 14 months in samples of contaminated soil and deduced from this that the infection could exist on the premises from one season to the next. Kerr (1930) observed that S. pullorum remained viable in fecal emulsions for more than 3 months. It appears that soil in runs or yards inhabited by infected flocks should be considered unsafe for pullorum-free stock. Placing such stock on new ground is a highly effective means against contracting the disease from contaminated soil. Frequent plowing and liming of contaminated soil will aid in the destruction of the organism.

5. Offal from all birds dressed for market or home consumption, as well as dead birds that are unfit for consumption, should be burned. Feeding of garbage should be avoided.

6. Eggs should not be saved for hatching until after a flock has been tested and found to be free of the disease. As long as infected birds are detected in a flock, one may anticipate losses from the disease among the progeny.

7. Fresh and infertile eggs from unknown or infected sources should not be fed to chickens or exposed to animals such as crows, sparrows, rats, and skunks which may carry or spread the infection. Investigations (Van Roekel et al., 1932) definitely reveal that infection may be contracted from such sources.

8. Poultrymen should not custom batch for untested or infected flocks (including fowl other than chickens) in view of the fact that the infection can be transmitted

through the incubator. This likewise applies to commercial hatcheries. Only hatching eggs from officially recognized clean flocks should be selected by commercial hatcherymen. Ample pullorum-clean stock is available to all hatcherymen, and there should be no compromise to hatch known infected stock. The hazard of transmission is too great. If this is not recognized and observed, progress in pullorum disease eradication will be greatly delayed.

9. Vigilance in the purchase of stock in the form of adults, chicks, and eggs from clean sources will reduce the number of "breaks" among tested flocks, and also will lessen the incidence of pullorum disease among specimens submitted to the laboratory. Official state agencies or their published lists of pullorum-free flocks should be consulted as a guide in the purchase of stock. Purchases should not be made on advertisements or sales literature alone, because of the lack of information or misleading statements. In recent years the production of started pullets has become a general practice. Frequently birds raised on different premises and originating from different breeder flocks are placed together on one farm as breeders. In numerous instances one is unable to trace the history

of the birds, and if a pullorum "break" occurs it is impossible to trace the source of the infection. This involved and complicated rearing practice adds further difficulty to an eradication program.

10. Birds removed from the premises to egg-laying contests and exhibitions should be held in quarantine and determined free of the disease before they are readmitted to the flock. In several instances the source of pullorum infection was traceable to contests and shows. Birds returned to the premises should be tested immediately upon their arrival and retested after 30 days' quarantine. The safest procedure is not to return such birds to the breeding flock in order to avoid introduction of other diseases as well as pullorum disease. Exhibition and fancier breeding flocks should be tested and reveal no infection before they are permitted entry into a poultry show. Since these exhibition birds may enter several shows in one season, they could serve as potential spreaders if infected.

11. Fowl other than chickens should be considered as a possible source of infection. The testing of such fowl may aid in determining their pullorum status. The eggs from chickens and from fowl other than chickens should not be hatched

TABLE 8.2

PULLORUM DISEASE TESTING SUMMARY OF 14 STATES COVERING A 35-YEAR PERIOD*

Item	1927–28†	1939–40	1950–51	1962–63
Chickens on hand	....	73,875,000	93,179,000	76,174,000
Number of tests	735,851	5,032,290	13,798,239	11,352,111
Percentage of positive tests (based on birds)	5.05	1.56	0.21	0.0007

Birds in pullorum-clean flocks	257,577	13,302,642	33,517,824

[a] The National Poultry Improvement Plan, 1963.

simultaneously in the same incubator. This precaution will avoid the spread of paratyphoid infections as well as pullorum disease among the different species of fowl.

12. Used feed bags and other equipment that may have been exposed to or contaminated with infective material should not be used unless properly cleaned and disinfected. Dunlap (1931) reported transmission of the disease to chicks which were fed mash from an artificially contaminated bag. The chance of processed feeds introducing pullorum infection cannot be ignored and further investigation is needed concerning this phase of the problem.

13. Poultry vaccines should be prepared from embryonating chicken eggs that are selected from pullorum-clean flocks. Fowl pox vaccine prepared from infected eggs has been responsible for extensive pullorum infection in vaccinated breeding flocks. As few as ten organisms per cubic centimeter of vaccine were able to infect chickens (Anon., 1951).

Eradication appears possible. Phenomenal progress in pullorum disease control and eradication has been made in the past decade (Van Roekel, 1964). In all sections of this country certain states have reduced the incidence of pullorum infection to a very low level (Tables 8.2 and 8.3). Some states, especially in the northeast, have reported no reactors among the tested flocks (Table 8.4). Also, the incidence of infection among specimens submitted to the diagnostic laboratories has declined to a very low figure. A number of states have not identified pullorum infection in either tested flocks or among specimens

submitted for examination to the diagnostic laboratory (Tables 8.5 and 8.6). The records reveal that pullorum disease is gradually being eliminated from poultry

submitted for diagnosis.

flocks and that the disease is amenable to
complete eradication.

The poultry industry and those agencies
which have been concerned with control
and eradication are to be commended for
the progress that has been made in re-
ducing the level of pullorum infection in
this country. This has been accomplished

on a limited voluntary basis. However,
since pullorum disease is amenable to erad-
ication it will require certain regulatory
measures implemented by state and federal
disease regulatory agencies to bring about
complete eradication on state and national
levels. Some states have in recent years re-
vised their disease laws in order to further
the control and eradication of pullorum
infection. Groups of states with the co-
operation of the federal government are
considering area plans for the eradication
of the disease.

The poultry industry can benefit from
the eradication programs applied to other
types of livestock. State and federal disease
regulatory agencies are actively engaged in
animal health programs and can give valu-
able assistance to the control and eradi-
cation program for pullorum disease. In
fact, a number of states have recognized the
wisdom of including poultry diseases in
their over-all animal disease control pro-
gram and have taken progressive steps to-
ward improving poultry health.

In view of the outstanding progress that
has been made in eliminating pullorum
disease from the nation's poultry flocks and
the increased interest manifested in total
eradication, it is hoped that all states will
strive toward the same goal. This will re-
quire the fullest cooperation from the in-
dustry as well as all other agencies that can
contribute to this goal.

Paratyphoid and Arizona Infections

Paratyphoid Infections

Paratyphoid infections, as the term is used with reference to poultry, denote a large group of acute or chronic bacterial diseases caused by one or more of the normally motile members of the *Salmonella* genus. For purposes of discussion the nonmotile organisms, *Salmonella pullorum* and *Salmonella gallinarum*, causative organisms of pullorum disease and fowl typhoid, respectively, are generally grouped separately from the paratyphoids. Salmonellosis is often used synonymously with "Salmonella infection" as an inclusive term to designate a disease caused by any one or more members of the *Salmonella* genus. *S. pullorum*, *S. gallinarum*, or a paratyphoid organism such as *S. typhi-murium* may independently or together be the cause of salmonellosis. Chronic intestinal carriers of paratyphoid infections are common; however, the disease seldom occurs in the acute, septicemic form except in young fowl or in mature birds under stress conditions such as virus diseases, inadequate diet, or unsanitary environment.

With the rapid expansion of the poultry industry, paratyphoid infections have become one of the most important groups of bacterial diseases affecting poultry, particularly turkeys. Furthermore, domestic poultry constitutes the largest single reservoir of *Salmonella* organisms existing in nature. As this disease recognizes no international boundaries and few host barriers, nationwide programs to eradicate it have not been attempted. Economically, paratyphoid infections are of most concern to commercial hatcherymen and those engaged in domestic poultry raising. Pet store owners, zoological park directors, pigeon and fancy bird raisers, and those interested in wild game are also concerned with the disease. These diseases, as they occur in poultry and poultry products, are also of very significant interest to those engaged in work in the field of public health.

HISTORY

Moore (1895) recorded the first authentic case of paratyphoid infection in domestic poultry in describing an outbreak of infectious enteritis in pigeons due to a bacillus of the hog cholera group. With improvement of culture procedures for the isolation of Salmonella and a better definition of the characteristics of members of the genus, the frequent association of paratyphoid organisms with disease outbreaks in all types of poultry, as well as other animal species and man, was rapidly established. Rettger et al. (1933) first reported on the occurrence of paratyphoid infections in turkey poults in the United States. Pomeroy and Fenstermacher (1939) observed the infection in Minnesota turkeys in 1932.

The numerous contributions of Dr. P. R. Edwards of the United States Public Health Service, and his colleagues, to knowledge on the incidence, distribution, and antigenic typing of paratyphoid and Arizona infections of fowl in the United States will be cited in later sections of this chapter. Dr. Edwards' laboratory has served as a constant reference point for research and disease control scientists interested in Salmonella infections in this country and abroad. Much valuable information, providing a basis for the systematic classification of the paratyphoid infections of poultry, has been contributed by Dr. Edwards and his co-workers since the early 1930's. Furthermore, paratyphoid infections as they occur in poultry have been related to those occurring in other animal species and man.

Knowledge and interest in the field of paratyphoid infections of fowl in the United States have also been advanced by the North Central Regional Poultry Disease Conference, organized in 1950. This conference is composed of research, diagnostic, and regulatory representatives from 12 states. The North Central States Conference has sought to develop and standardize the cultural and serological methods for the study and control of Salmonella infections of poultry.

There has never existed any official national program for the eradication of paratyphoid infections of poultry such as that in operation for the eradication of pullorum disease and fowl typhoid under the National Poultry and National Turkey Improvement Plans (Anon., 1963b). The latter Plans do provide, however, that the official state agency may at its own discretion take paratyphoid infections under consideration in determining the pullorum-typhoid status of a flock. The National Plans maintain a Committee on Salmonellosis and Related Enteric Diseases of poultry which advises on technical matters relating to these infections. The Animal Disease Eradication Division of U.S.D.A. in cooperation with the National Plans has instituted a Salmonella reporting and investigative service dealing with these infections as they occur in poultry flocks in the various states.

ETIOLOGY

The paratyphoid group of bacteria is included in the large family *Enterobacteriaceae* and is composed of approximately 800 serological types belonging to the genus *Salmonella*, each with a specific type designation. The rapidity with which new types have been added to the ever expanding list of paratyphoids is illustrated by the fact that only about 150 types were recognized at the time of the 1952 edition of this book.

Current procedure is to name Salmonella according to the state or province in which they are first isolated. If this name has already been used, the name of the town where the isolation was first made is employed as the basis for nomenclature. This system of naming members of the *Salmonella* genus has resulted in a list of type designations representative of centers of population in every part of the world.

Organisms of the paratyphoid group are defined as serologically related, Gram-negative and nonsporogenic bacilli: 0.4–0.6 by 1–3 micra in usual dimensions but occasionally forming short filaments. They are

normally motile by means of peritrichous flagella, but nonmotile variants are occasionally encountered under natural conditions. Edwards et al. (1946) and Hirsch (1947) reported some strains of Salmonella that appeared to be nonmotile while possessing well-developed flagella and flagellar antigens.

Paratyphoids are facultative anaerobes and can be readily cultivated on initial isolation, from sources other than feces, on simple beef extract and beef infusion agars and broths. Optimum growth temperature is 37° C. When it is desired to obtain large yields of the organisms, media enhanced with serum, dextrose-starch, brain-heart infusion, beef heart infusion (McNeil and Hinshaw, 1951), colloidal sulfur and glycerin (MacDonald, 1947), or cysteine hydrochloride and glycerin (Harris and Williams, 1957) can be used.

Smooth broth cultures after incubation for 24 hours show a thick, homogeneous turbidity with no pellicle and very little sediment. Rough cultures in broth have a heavy, granular sediment and an almost clear supernatant fluid. Felix and Pitt (1935) working with S. typhi were able to produce rough strains by plating broth cultures which had been maintained at room temperature for several months. Stable rough strains were obtained by Béguin and Grabar (1953) through acetone treatment. Rough to smooth transformations of paratyphoid cultures are not easily accomplished. Animal passage of cultures and treatment with guinea pig complement, as cited by Kauffmann (1950), have been used for obtaining smooth cultures. In order to avoid the development of rough cultures, Kauffmann (1950) recommended that media employed for the storage of cultures should contain no carbohydrates, and subculturing should be done as infrequently as possible. Lyophilization is the best method to prevent roughness of cultures.

Typical colonies of paratyphoids on agar culture are round, slightly raised, and glistening with smooth edges. Colonies are generally 1-2 mm. in diameter depending on the degree of dispersion on the plates. Rough (R) colonies may be encountered both among recently isolated strains and those maintained in the laboratory on artificial media. R forms are dull and granular with irregular edges. From a practical standpoint, it is usually assumed that morphologically rough strains of Salmonella do not contain smooth antigens and such cultures cannot be typed serologically or used in the preparation of antigens for the agglutination test. Attempts have been made to distinguish rough cultures by testing cell agglutinability in saline or trypaflavine (Pampana, 1933), or determining color changes in cell masses suspended in Millon's reagent (White, 1929). None of these methods is entirely satisfactory. Study of colonial morphology and observation of growth in broth are perhaps the most practical procedures that can be followed in the laboratory. Kauffmann (1950) cited serological procedures as the only absolute methods to determine if a culture contains normal smooth antigens.

The following properties, as described by Edwards and Ewing (1962), are typical of practically all members of the paratyphoid group:

Dextrose — Fermented with gas
Lactose — Not fermented
Sucrose — Not fermented
Mannitol — Fermented with gas
Maltose — Fermented with gas
Dulcitol — Usually fermented with gas
Salicin — Not fermented
Sorbitol — Fermented with gas
Adonitol — Not fermented
Inositol — Fermented or not fermented
Indol — Not produced
Methyl Red — Positive
Voges-Proskauer — Negative
Simmons' Citrate — Usually utilized
H_2S — Usually positive
Urea — Not hydrolyzed
Gelatin — Rarely liquefied
KCN — Negative
Nitrates — Reduced
Motility — Positive
Decarboxylases

Lysine — Positive
Arginine — Positive, usually delayed
Ornithine — Positive
Malonate — Negative
Phenylalanine deaminase — Negative

Cultures that do not possess the above characteristics may be excluded from the paratyphoid group unless it can be established that they possess antigens of known Salmonella types. It is not presently customary, however, to include certain Arizona strains possessing Salmonella antigens in the paratyphoid group. S. typhi-murium var. copenhagen, a frequent cause of paratyphoid infection of pigeons, occasionally forms no acid and, more frequently, no gas in maltose broth. Consequently this organism is sometimes confused with S. pullorum on initial examination.

Because of the delayed fermentative properties characteristic of certain enteric organisms, such as the Arizona, prolonged incubation of fermentation broths for three weeks or longer is often advantageous. Sealing of the tubes with cork stoppers dipped in hot paraffin will hasten the reactions. Basal carbohydrate broths with Andrade's indicator have been very widely used for many years in the identification and study of Salmonella cultures. Kauffmann (1950) recommended a basal 1 per cent peptone broth with bromthymol blue as an indicator. Bromcresol purple has also been used by some laboratories as an indicator in the study of Salmonella cultures.

Motility of paratyphoid cultures can be readily demonstrated through the use of semisolid medium as described by Edwards and Ewing (1962). This medium is also useful in the separation of flagellar phases for the preparation of antigens or typing sera.

RESISTANCE AND VIABILITY OF PARATYPHOID ORGANISMS

Paratyphoid organisms are quite susceptible to heat and the majority of the common disinfectants. Most members of the group, suspended in saline, are de-

stroyed by a temperature of 60° C. in approximately 15 minutes. Bierer and Barnett (1961) demonstrated that washing eggs, the shells of which were contaminated with S. typhi-murium, for either 3 minutes or 1 minute at 65° C. resulted in 99.5–100 per cent kill of the organisms. Cresylic acid and lye are frequently employed in the disinfection of poultry premises. Formaldehyde is also widely used as a disinfectant, particularly as a fumigant for incubators and hatchery rooms. Lancaster et al. (1952) reported that S. thompson and S. typhi-murium were more resistant than S. pullorum to the effects of several disinfecting solutions studied.

Hashimoto (1961) found S. senftenberg, in contrast to S. pullorum, to be resistant to the bactericidal properties of egg albumen, yolk, and various embryonic fluids. Watanabe et al. (1959b) demonstrated that embryonic fluid and serum had no bactericidal effect on S. senftenberg. Anellis et al. (1954) reported that in egg albumen Salmonella organisms were more rapidly destroyed by heat at a high pH, and Banwart and Ayres (1957) found that raising the pH of egg albumen to 9 or 10 caused a reduction in the number of surviving Salmonella organisms during processing of the product. Lerche (1957) noted that the addition of 0.25–0.5 per cent of ammonia was necessary to destroy Salmonella in egg white. Simskaya (1955) demonstrated that the inactivation of amylase in duck eggs can be used as an index or confirm the destruction of Salmonella organisms in such eggs following heat treatment.

Watts and Wall (1952) found that S. typhi-murium could survive for at least 119 days in ponds in Australia. Kraus and Weber (1958) demonstrated that Salmonella organisms could survive from several weeks to 3 months in drinking water and natural surface water, being affected independently by the nutritional conditions and the temperature of the water. Adler et al. (1953) were able to isolate S. typhi-murium from litter 44 days after experimental infection of poults which were allowed to run on the litter. Felsenfeld and

Young (1945) demonstrated that Salmonella could survive for several weeks on vegetables kept at room temperature. Steiniger (1961), in the examination of 100,000 samples of birds' feces found in nature, reported that Salmonella were more frequently isolated from feces found on vegetation than on stones and soil. Salmonella survived for 28 months on plant material allowed to dry slowly. It was concluded that fodder grown in fields sprayed with sewage effluent should not be mixed with concentrates that would favor the multiplication of Salmonella.

Mair and Ross (1960) reported that *S. typhi-murium* was found to survive in urban garden soil in England for at least 280 days, the extent of their study. Slavkov (1961) found that Salmonella organisms survived in soil for 120–150 days depending on pH, temperature, and the presence of nutrients or inhibitors. Price *et al.* (1962) cited information to indicate that Salmonella organisms may remain viable in duck feces for 28 weeks. Malathion in fly sprays was not found to kill the organisms in feces. Sylwester (1961) reported that *S. typhi-murium* remained viable in dried pupae of Calliphora flies for a period of one year.

Pomeroy and Fenstermacher (1939) found that paratyphoid organisms survived in turkey eggshells at incubator temperature for at least 11 months; in feces at incubator temperature from 77 days to 11 months; on eggshells at 50° F. from 191 to 346 days; on eggshells exposed to the varying conditions of the elements for 135 to 350 days depending upon the organism. The same investigators (1941) demonstrated that *S. typhi-murium* could survive in the contents of turkey eggs at incubator temperature for a period of at least 13 months. Buxton and Gordon (1947) found that *S. thompson* could survive on the surface of chicken eggs for at least 21 days under ordinary conditions of storage at room temperature. Gregory (1948), using an incubator at a temperature of 100° F. and a wet bulb reading of 82°–86° F., found that the shell surface of 2 of 26 turkey eggs contaminated with *S. typhi-murium* remained infected after 28 days.

Huey and Edwards (1958) found that 9 per cent of *S. typhi-murium* strains isolated from poultry after 1956 were resistant to tetracyclines when compared with other cultures isolated prior to 1948. They attributed this to the use of antibiotics in poultry feeds. In further studies, Ramsey and Edwards (1961) found that 29 of 100 *S. typhi-murium* cultures isolated from fowls in 1959 and 1960 were resistant to the tetracyclines. Garside *et al.* (1960) demonstrated a tenfold increase in resistance to chlortetracycline in the case of a single colony inoculum of *S. typhi-murium* administered to chicks receiving the antibiotic in their diet. The organisms were capable of resisting 210 p.p.m. of chlortetracycline after 4 passages. Subsequent passage of the resistant cultures through chicks receiving no drug in their feed revealed that resistance declined gradually, but at the end of 14 weeks some strains were still 4 times as tolerant to the antibiotic as the normal strains. Hobbs *et al.* (1960) found that a strain of *S. typhi-murium* resistant to chlortetracycline grew more rapidly than spoilage organisms at 22° C. on the skin of dressed poultry that had been immersed in slush ice containing 10 p.p.m. chlortetracycline.

Lancaster and Crabb (1953a) reported that *S. typhi-murium* and *S. thompson* rapidly lose their viability on the shell of whole chicken eggs maintained under normal incubator temperature. At room temperature the organisms were found to survive for approximately 21 days on clean eggs and for a longer period on artificially dirty eggs. Increased humidity prolonged the viability of the organisms. Watanabe *et al.* (1959a) found that *S. senftenberg* survived for 10 days on the surface of the eggshell at room temperature. In the incubator the organism penetrated the shell in 4 to 8 days and was found to penetrate more rapidly through eggshells that were filed. Embryos which were invaded by *S. senftenberg* through the shell stopped their development and could not hatch.

NATURAL DISTRIBUTION, INCIDENCE, AND ECONOMIC IMPORTANCE

Paratyphoid infections of poultry exist in all parts of the world; however, it has often been found that particular serological types are more frequently encountered in one region than in another. Wilson (1948) called attention to the occurrence of 24 new Salmonella types encountered in human cases of food poisoning in Great Britain. Six of these types were commonly found in poultry in the United States; however, they had not been found in Great Britain prior to the large scale importation of egg powder during World War II.

Certain Salmonella types have become widespread in a country or an area for a given period of time, and then decreased in incidence to a point of little importance. Gordon and Buxton (1946) noted that S. thompson was first encountered in poultry in Great Britain in 1943, and subsequently ceased to be a problem. Buxton (1957a) stated that S. oranienburg, S. bareilly, and S. montevideo are more frequently isolated from poultry in the United States than in European countries, while S. enteritidis occurs more frequently among poultry in European South countries than it does in North and South America.

Extensive surveys have been conducted to determine the incidence of the various serological types of Salmonella existing in poultry in the United States. Edwards (1939) listed 16 types of Salmonella recovered over a 5-year period from 100 separate outbreaks among poultry. Bruner and Edwards (1941) examined 900 cultures serologically and found 64 of this number were members of the paratyphoid group. Ninety-two per cent of these cultures were isolated from fatal infections of fowl. Edwards and Bruner (1943) examined several thousand cultures of Salmonella obtained from many areas in the United States. They did not subdivide the fowl into their respective species; however, 42 Salmonella types were found in poultry. Pomeroy and Fenstermacher (1941) recorded the isolation of 20 Salmonella types

from turkey poults in Minnesota. Pomeroy (1944) listed 24 Salmonella types recovered from poults in Minnesota. S. typhi-murium was found in approximately 75 per cent of the paratyphoid outbreaks. Fenstermacher (1952) listed 40 types that had been isolated from turkeys in the Minnesota laboratory.

Hinshaw et al. (1944) listed a total of 48 Salmonella types isolated from poultry in the United States. Edwards et al. (1948a, 1948b) examined 12,831 cultures of Salmonella that had been isolated during the period 1934–47 from 47 animal species (including fowl, reptiles, lower mammals, and man) and from other sources.

Edwards et al. (1948c) reported on the serological analysis of 6,587 Salmonella cultures isolated from fowl. Practically all of the cultures were derived from acute, fatal infections of young birds. A small number were isolated from adult birds affected with acute infections and many others from the intestines of adult chickens that were apparently normal carriers. Fifty-eight different Salmonella types, exclusive of S. pullorum and S. gallinarum, were recovered from fowl. S. typhi-murium was encountered most frequently producing 30.8 per cent of the outbreaks and composing 37.7 per cent of the cultures. It was concluded that any Salmonella type other than those types showing strict host adaptation, such as S. typhi and S. abortus-equi, may under proper circumstances cause highly destructive diseases in poultry. No correlation was found between the type of Salmonella isolated and the severity of the disease; however, it was felt that such types as S. typhi-murium, S. oranienburg, S. montevideo, S. bareilly, and S. newport usually produced the highest percentages of mortality.

Perelli-Minetti et al. (1948) reported the isolation of 28 types of paratyphoid from chickens and turkeys over a period of 6½ years in the poultry diagnostic laboratories of California. Of a total of 167 turkey isolations, 58.6 per cent were types other than S. typhi-murium. Of 12 cases in adults, 91.6 per cent were S. typhi-mu-

rium. Smith (1959) cultured the intestinal walls of 280 normal chickens in Essex, England, and was unable to isolate *Salmonella* from any of the samples.

Lukas and Bradford (1954) reported that paratyphoid infections were responsible for approximately 21 per cent of the disease problems with which the turkey growers in the Turlock area of California were concerned during the first 6 months of 1952. A total of 241 cultures of paratyphoid organisms, representing 30 serological types, was isolated from turkey poults on routine necropsy. *S. typhi-murium* accounted for 46.5 per cent of the uncomplicated paratyphoid outbreaks. Pomeroy *et al.* (1957a) found that 15 per cent of the consignments of poults received in the Minnesota laboratory in 1956 were infected with paratyphoid.

Moran (1959a) cited typing data which indicated that *S. typhi-murium* was encountered four times as frequently in turkeys as in chickens in the United States in 1957 *S. heidelberg* and *S. infantis*, which had not been reported in fowl in the United States in the earlier report of Edwards *et al.* (1948c), comprised 8 per cent and 6.7 per cent, respectively, of the cultures from chickens. Moran (1960) found that of 1,178 *Salmonella* cultures typed from animals during 1958, 87.2 per cent were from avian sources. Sixty-nine types were identified, 40 of which occurred in turkeys and 32 in chickens. Moran (1961b) reported the isolation of 57 types of *Salmonella* from turkeys and 52 types from chickens in the United States during a survey period of 4½ years (1957–1961). *S. typhi-murium* was by far the most common and accounted for 22 per cent of all *Salmonella* types encountered in animals. *S. typhi-murium* cultures isolated from turkeys outnumbered those from chickens by about 2 to 1.

A total of 117 paratyphoid types that have been isolated from chickens and/or turkeys in the United States are listed in Table 9.1. Fifteen new types not previously reported from poultry in the United States have been added to the list since the

fourth edition of this book. The information included in the table has been developed from published reports and from data supplied by diagnostic laboratories, typing centers, and research workers in various parts of the country. While the listings may be incomplete, it is considered that most types that have been reported prior to 1964 from chickens and turkeys are represented. As additional laboratories are encouraged to submit cultures for typing, the listings will undoubtedly be considerably increased. Some of the types listed in Table 9.1 have not been associated with disease outbreaks, but were recovered from the intestines of birds that were apparently normal carriers. However, most of the cultures were derived from acute, fatal infections in young chicks or poults, and were isolated from the internal organs or intestinal contents. Isolations from unabsorbed yolks, ovarian cysts, and oviducts represent only a small percentage of the culture types listed. Original references to the description of most of the *Salmonella* types included in Table 9.1 are listed by Kauffmann (1954).

Buxton (1957a) in a comprehensive review of salmonellosis in poultry, presented a worldwide survey of *Salmonella* types occurring in poultry. A total of 90 types of paratyphoid organisms was reported from 12 species of fowl. Many of these serotypes were reported to have caused only a few minor epizootics and some to have been isolated only from apparently healthy birds. The reader seeking reference material on the host species, origin, and distribution of *Salmonella* types occurring in poultry in various parts of the world is referred to this excellent review.

Some of the *Salmonella* types isolated from poultry in other parts of the world that have not yet been reported from fowls in the United States include *S. bonariensis, S. brancaster, S. brandenburg, S. chicago, S. goettingen, S. sturi, S. lille, S. mbandaka, S. ness-ziona, S. oslo, S. schleissheim,* and *S. weybridge.*

Lerche (1939) reported the following types have been isolated from poultry in

S. dublin	S. lumia	S. rubislaw	

Germany: *S. typhi-murium, S. enteritidis* Gaertner (vars. Essen and Kiel), *S. cholerae-suis, S. newport, S. senftenberg, S. oranienburg,* and *S. anatum.* Sedlmeier et al. (1957) found 46 different Salmonella types among chickens in Germany. These were described as human-pathogenic types. Hygienic measures necessary to control or eliminate these infections were described. Feils (1957) reported the identification of 300 cultures of Salmonella from poultry in Germany. *S. bredeney, S. bareilly, S. infantis, S. binza, S. typhi-murium,* and *S. anatum* were among the types isolated. Possible importation of these organisms in protein animal feeds was mentioned, and the public health significance of these infections was emphasized. Hansen (1942), in Scandinavia, studied 308 cultures isolated from poultry, 303 of which were *S. typhi-murium,* 3 *S. enteritidis* (var. Essen), and 2 were *S. dublin.* Henning (1939), following a study of salmonellosis in South Africa, reported that *S. typhi-murium, S.*

anatum, S. amersfoort, and S. typhi were recovered from poultry.

Kampelmacher (1963) reported that with the exception of ducks, poultry surprisingly has not been found so far to constitute an important reservoir of Salmonella organisms in the Netherlands. Marthedal (1962) noted the marked increase of Salmonella infections in poultry in Denmark since 1944. The large number of new types found have been ascribed mainly to imported meat and bone meal that has not been sufficiently heated. Das et al. (1959) stated that the incidence of avian salmonellosis is increasing in India. Perek and Rabinovitz (1957) reported that 12 Salmonella types have been isolated from poultry in Israel.

Atkinson (1956) reviewed the serological typing of 3,340 Salmonella cultures in Australia during the period 1944–1954. Fifty-nine different Salmonella types were found with *S. typhi-murium* and *S. bovis-morbificans* being the most common types iso-

lated from both humans and animals.

Gordon and Buxton (1946), in a study of avian salmonellosis in Great Britain, found during the period 1933–44 that of a total of 6,578 groups of young birds examined, 4.1 per cent were infected with Salmonella organisms other than *S. pullorum* and *S. gallinarum*. The types of paratyphoid organisms isolated were *S. typhi-murium*, *S. thompson*, *S. enteritidis*, *S. california*, *S. bareilly*, *S. montevideo*, and *S. anatum*. Gordon (1959) reported that up to 1959, 50 types of Salmonella have been isolated from poultry in Great Britain. Several types not previously reported have been isolated from chickens; however, these new types have not tended to become established in poultry flocks and outbreaks due to them are restricted.

Bigland et al. (1962) reviewing Salmonella isolations from Alberta, Canada, for the years 1949 to 1960, reported a total of 22 types of paratyphoid, with 1,227 of a total of 1,242 isolations from avian species being made from turkeys and chickens. *S. heidelberg*, first isolated in Alberta in 1952, has been the most commonly isolated Salmonella type of avian origin for several years. Sakazaki et al. (1959) examined a total of 2,482 Salmonella and 16 Arizona cultures isolated from man and animals in Japan from 1949 to 1957. Fifty-eight types of Salmonella and 9 types of Arizona were identified. *S. senftenberg* was the most frequent Salmonella type isolated from fowl in contrast to the situation in the United States. Three Salmonella types which seem to be exclusive for Japan were repeatedly isolated. Arizona strains were cited as rare in Japan, and none of those isolated came from poultry.

The epizootiology of Salmonella infections among individual flocks is often complex due to the wide distribution of the organisms in fowl and the practice of bringing the eggs from different flocks together in one hatchery. Edwards and Bruner (1940) described an extensive study of multiple types of paratyphoids in individual flocks. Pomeroy and Fenstermacher (1941) reported that from one farm where poults had been accumulated from several sources over a period of 3 years, *S. typhimurium*, *S. derby*, *S. give*, *S. oranienburg*, *S. senftenberg*, and *S. anatum* were isolated. From the same farm in previous years other Salmonella types had been isolated. Hinshaw et al. (1944) also reported multiple types of salmonellosis on the same ranch.

Edwards et al. (1948a) found more than one Salmonella type existing in the same flock in 165 instances. Akiyama et al. (1959) isolated 4 Salmonella types from a group of 7-day-old chicks that were also found to be infected with *S. pullorum*. It was assumed that the organisms infected the eggs during incubation. Ballantyne (1953) reported the isolation from one turkey farm of 4 different serological types of Salmonella. Boyer et al. (1962) reported multiple Salmonella types in several individual cases of salmonellosis in both chicks and poults. It was noted that simultaneous infections are not unusual.

The isolation of 2 or more Salmonella types from a single bird was reported by Edwards et al. (1948a, b) in 51 cases of avian paratyphoid infections. Four Salmonella types were recovered from the liver of one poult, and 3 from the liver of a second.

From an economic viewpoint paratyphoid infections are among the most important bacterial diseases of the hatching industry and result in high death losses among all types of young poultry. The occurrence of this disease in valuable breeding stock is extremely costly. Because of its chronic nature and difficulty of eradication it is capable of terminating breeding operations in which large amounts of money may have been invested. Fertility, hatchability, and egg production may be seriously impaired (Graham and Michael, 1936; Pomeroy and Fenstermacher, 1941). The disease has a definite stunting effect on surviving birds and a debilitating influence on poultry of all ages increasing their susceptibility to many diseases.

SEROLOGY OF THE PARATYPHOID GROUP

Paratyphoid organisms have been subjected to detailed antigenic study. The approximately 800 serological types presently recognized are listed in the Kauffmann-White diagnostic schema. Most Salmonella organisms possess both somatic (O) and flagellar (H) antigens. The O antigen is associated with the bacterial cell proper and is resistant to both alcohol and heat treatment. The H antigen is a part of the flagella and is both alcohol- and heat-labile. The various O antigenic factors are designated with arabic numerals while the H antigenic factors are divided into phases 1 and 2, which are designated with small letters and arabic numerals, respectively. Thus, the complete antigenic formula of S. typhimurium is 1, 4, 5, 12 (O): i, 1, 2 (H). Marthedal (1962) reported a variation in the somatic antigens of cultures derived from 320 outbreaks of S. typhimurium infection in poultry in Denmark. Factors 4, 5, and 12 were easily demonstrated in most cultures; however, factor 1 was variable.

Highly specialized serological procedures have been developed for the antigenic analysis and classification of Salmonella cultures. In conducting the antigenic analyses, sera containing agglutinins for specific antigenic factors are used in macroscopic plate and tube agglutination tests to determine, first, the O and, subsequently, the H antigenic structure of each culture. After the O and H antigenic factors of a culture have been determined its identification merely requires reference to the Kauffmann-White schema. The schema includes 10 main serological groups, with groups C and E possessing additional subgroups.

Most poultry diagnostic laboratories do not find it practical to engage in the serological analysis of Salmonella cultures, but rather rely upon the U.S.D.A.'s National Animal Disease Laboratory, Ames, Iowa; the State Health Department Laboratory; or the Communicable Disease Center's Enteric Bacteriology Laboratory, Atlanta, Georgia, for this service. It is strongly recommended that all Salmonella cultures isolated from poultry be sent to Diagnostic Services, National Animal Disease Laboratory, Box 70, Ames, Iowa, for typing. This will permit cultures of avian origin to be examined at one central laboratory for better correlation, review, and distribution of results as accumulated. Thus, accurate, current information on the incidence and distribution of Salmonella types among poultry will be available to guide the formulation of control programs for those found to be of most importance.

Polyvalent sera for examination of Salmonella and Arizona cultures are very useful in preliminary culture screening. These sera are generally employed in rapid slide tests in a suitable dilution, and agglutination is easily read. Some are available commercially. Kauffmann and Edwards (1947, 1957) described simplified methods for the serological identification of the most important Salmonella types. Edwards et al. (1948c) found that 99.5 per cent of all Salmonella types from fowls that they examined belonged to groups B, C, D, and E or were S. worthington or S. minnesota. This prompted them to suggest that a polyvalent serum covering the somatic and frequently occurring flagellar antigens of the above four groups and S. worthington and S. minnesota would be very helpful in the diagnosis and study of avian salmonellosis. Bruner (1957) described the preparation of a polyvalent Salmonella typing serum by injecting rabbits with a mixed formolized broth antigen representative of the known components of the Salmonella antigenic mosaic.

There is marked variation in the somatic and flagellar antigenic structure of Salmonella types infecting poultry. The antigenic formula of each of 117 types of paratyphoids isolated from turkeys and chickens in the United States is listed in Table 9.2. Organisms representative of all

*Indicates that this antigen may be absent.

the major antigenic groups in the Kauff-mann-White schema, with the exception of serological group A, have been isolated from chickens and turkeys.

Approximately 80 per cent of all Salmonella types isolated from turkeys and chickens in the United States are members of antigenic groups B, C, D, and E. The greatest number of paratyphoid types belong to group C followed by groups E, B, and D in sequence. Because of the very frequent occurrence of S. typhi-murium in paratyphoid outbreaks in turkeys in the United States, the greatest number of cultures isolated is representative of serological group B.

As illustrated in Table 9.2, organisms within a given serological group share common somatic antigens. Flagellar antigens are also shared within and between groups. An example of the existence of common somatic antigenic factors in two separate groups of the Kauffmann-White schema is illustrated by organisms in groups B and D, which both possess antigen 12. This common somatic antigen accounts for the fact that chickens and turkeys infected with S. typhi-murium (1, 4, 5, 12) or some other member of group B, may be detected when tested with S. pullorum (9, 12) antigen. As would be expected, the serum titer of birds infected with S. typhi-murium is lower when tested with pullorum antigen than with a homologous antigen.

Hinshaw and McNeil (1943a) found that the 1-25 dilution tube agglutination test for pullorum disease in turkeys will detect about 25 per cent of the S. typhi-murium reactors because of the cross agglutination in antigen 12. Bierer and Vickers (1960a) found the pullorum whole-blood and tube agglutination tests to be of little value in detecting birds infected with S. typhi-murium. Burr et al. (1957) found that approximately 50 per cent of a group of 13 chickens, artificially infected with S. heidelberg (4, 5, 12), revealed no titer to S. pullorum tube agglutination antigen at a 1-25 dilution, but gave at least a 2+ reaction at the same dilution with S. heidelberg antigen. Chang et al. (1957) found

that removal of the Bursa of Fabricius in young chickens reduced antibody production following inoculation of S. typhi-murium antigen.

Bahr and Christensen (1933), Van Roekel and Bullis (1937), Pomeroy and Fenstermacher (1944), Hinshaw and McNeil (1944a), and Becker (1957) have discussed the difficulties that are encountered in testing chickens and turkeys for the control of pullorum disease when certain types of paratyphoid infections are present in flocks. Wilson (1947) reported the isolation of S. typhi-murium from two chickens that reacted with pullorum antigen.

PATHOGENICITY

Most death losses from paratyphoid infections of poultry are encountered during the first two weeks after hatching with the highest losses occurring between the sixth and tenth day. The infection seldom causes severe mortality in birds more than one month old. Pigeons, parakeets, and canaries may be cited as exceptions, for the disease does occur more frequently in the acute form in adults of these species.

Mortality rates among broods of young birds under natural conditions usually vary from negligible to 10 or 20 per cent; however, mortality rates of 80 per cent or higher are encountered in severe outbreaks. The pathogenic properties of Salmonella are due to endotoxins which are closely associated with the somatic portion of the organism. Buxton (1958) called attention to the fact that nutrition may have a significant effect on the susceptibility of animals to Salmonella infections and may be associated with factors concerning the development of immunity in the host and alterations in the virulence of the infecting organism.

Adult birds infected with paratyphoid organisms generally show no outward symptoms; however, they may serve as intestinal carriers of the infection over long periods of time. Paratyphoid infections exhibit little or no selectivity in their pathogenicity for specific strains or breeds of birds.

*( ) Indicates that this antigen may be absent.

the major antigenic groups in the Kauffmann-White schema, with the exception of serological group A, have been isolated from chickens and turkeys.

Approximately 80 per cent of all Salmonella types isolated from turkeys and chickens in the United States are members of antigenic groups B, C, D, and E. The greatest number of paratyphoid types belong to group C followed by groups E, B, and D in sequence. Because of the very frequent occurrence of *S. typhi-murium* in paratyphoid outbreaks in turkeys in the United States, the greatest number of cultures isolated is representative of serological group B.

As illustrated in Table 9.2, organisms within a given serological group share common somatic antigens. Flagellar antigens are also shared within and between groups. An example of the existence of common somatic antigenic factors in two separate groups of the Kauffmann-White schema is illustrated by organisms in groups B and D, which both possess antigen 12. This common somatic antigen accounts for the fact that chickens and turkeys infected with *S. typhi-murium* (1, 4, 5, 12) or some other member of group B, may be detected when tested with *S. pullorum* (9, 12) serum antigen. As would be expected, the serum titer of birds infected with *S. typhi-murium* is lower when tested with pullorum antigen than with an homologous antigen.

Hinshaw and McNeil (1943a) found that the 1·25 dilution tube agglutination test for pullorum disease in turkeys will detect about 25 per cent of the *S. typhimurium* reactors because of the cross agglutination in antigen 12. Bierer and Vickers (1960a) found the pullorum whole-blood and tube agglutination tests to be of little value in detecting birds infected with *S. typhi-murium.* Burr et al. (1957) found that approximately 50 per cent of a group of 13 chickens, artificially infected with *S. heidelberg* (4, 5, 12), revealed no titer to a *pullorum* tube agglutination antigen at a 1·25 dilution, but gave at least a 2+ reaction at the same dilution with *S. heidelberg* antigen. Chang et al. (1957) found

that removal of the Bursa of Fabricius in young chickens reduced antibody production following inoculation of *S. typhimurium* antigen.

Bahr and Christensen (1933), Van Roekel and Bullis (1937), Pomeroy and Fenstermacher (1944), Hinshaw and McNeil (1944a), and Becker (1957) have discussed the difficulties that are encountered in testing chickens and turkeys for the control of pullorum disease when certain types of paratyphoid infections are present in flocks. Wilson (1947) reported the isolation of *S. typhi-murium* from two chickens that reacted with pullorum antigen.

PATHOGENICITY

Most death losses from paratyphoid infections of poultry are encountered during the first two weeks after hatching with the highest losses occurring between the sixth and tenth day. The infection seldom causes severe mortality in birds more than one month old. Pigeons, parakeets, and canaries may be cited as exceptions, for the disease does occur more frequently in the acute form in adults of these species.

Mortality rates among broods of young birds under natural conditions usually vary from negligible to 10 or 20 per cent; however, mortality rates of 80 per cent or higher are encountered in severe outbreaks. The pathogenic properties of Salmonella are due to endotoxins which are closely associated with the somatic portion of the organism. Buxton (1958) called attention to the fact that nutrition may have a significant effect on the susceptibility of animals to Salmonella infections and may be associated with factors concerning the development of immunity in the host and alterations in the virulence of the infecting organism.

Adult birds infected with paratyphoid organisms generally show no outward symptoms; however, they may serve as intestinal carriers of the infection over long periods of time. Paratyphoid infections in their exhibit little or no selectivity in their pathogenicity for specific strains or breeds of birds.

Pomeroy (1944) reported on the mortality of young poults experimentally infected with *S. typhi-murium* at 2 and 4 days of age. The mortality of the poults infected when 2 days old varied from 40 to 60 per cent, and that of the 4-day-old group was 40 per cent. Other experimental evidence indicated that the older the poults were when exposed, the lower was the expected mortality. Bierer (1960) found turkey poults extremely susceptible to *S. typhi-murium* infection during the first 48 hours after hatching. Mitrovic (1956) reported that 1-day-old turkey poults were very susceptible to experimental infection with *S. reading* with a mortality of 40 per cent, while 2-week-old poults possessed extremely high resistance to the infection. Yamamoto et al. (1961a) studied the shedding of Salmonella organisms in the feces of orally infected adult turkeys. They found that there was a marked decrease in the number of organisms shed by 14–21 days.

In contrast to poults, chicks usually do not exhibit high mortalities when infected experimentally. Watanabe et al. (1959b) in studies of the resistance of chick embryos to *S. senftenberg* infection found that the lethal dose of the organism increased in direct relation to the age of the embryos. Bliznakov et al. (1963) demonstrated that resistance of embryonated eggs to *S. typhimurium* infection may be qualitatively increased by antiserum, implantation of splenic tissue from normal or immune adult fowl, or by a combination of these treatments. Milner and Shaffer (1952) conducted detailed bacteriological studies of experimental Salmonella infections in chicks and were able to demonstrate that infection by the oral route decreased rapidly with advancing age. Fatality rates in the chicks experimentally infected were not high, although bacteremia was easily demonstrated through blood culture. Clemmer et al. (1960) found a wide variation in the response of chicks exposed to aerosol infection with various Salmonella types. *S. typhi murium* was found to be very invasive for lung tissue in contrast to the other

types studied. Beattie (1960) reported that *S. thompson* had no ill effects on chicks over 3 weeks of age without any therapeutic measures. Buxton and Gordon (1947) were able to produce a 44 per cent mortality in chicks infected orally with *S. thompson*. Approximately 70 per cent of the survivors remained intestinal carriers at 21 days of age.

Mitrovic (1956) found that either 1-day- or 2-week-old chicks were highly resistant to oral infection with *S. reading*. Sieburth and Johnson (1956) reported that orally administered *S. typhi-murium* organisms are very infective for the day-old chick with 100 per cent infection arising from 10^{20} and 50 per cent mortality from $10^{3.5}$ viable organisms per chick. Sieburth (1957a) was able to produce a cumulative mortality of 27 percent in chicks 12 days post inoculation by administering approximately 160 viable *S. typhi-murium* cells orally to each bird at 1 day of age. *S. typhi-murium* recovery from the intestine and organs was 100 per cent. Bierer (1961) found that *S. typhi-murium* infection could be induced experimentally in chicks by spraying broth cultures of the organism into incubators 1 day before hatching. Mortality was almost tripled in infected groups maintained in unheated brooders for a 10-day period. Hamada et al. (1958) found that chicks infected in the incubators usually acquire the infection through the respiratory and digestive organs, and carry the greatest concentration of the organisms during the first week of life. They may appear healthy and usually eliminate the infection in 4–6 weeks without therapy.

Shaffer et al. (1957) found marked variation in the response of day-old chicks to either peroral or parenteral inoculation with various antigenic types of Salmonella. The course of infection produced by *S. typhi murium* included marked shedding of the organisms in the feces; frequent invasion and localization in tissues such as the spleen, liver, and lungs; and deaths from bacteremia. *S. paratyphi A* exhibited less evidence of invasiveness and caused no mortality. Henderson et al. (1960) admin-

istered 7 different Salmonella serotypes orally in graduated doses to inbred White Leghorn day-old chicks. All 7 serotypes produced mortality varying from about 2 per cent (*S. anatum*) to 80 per cent (*S. typhi-murium*). Exposure to their own feces of chicks infected with *S. anatum* significantly increased but did not extend the period of mortality. Akiyama (1961) found that there was a low mortality rate in chicks artificially infected with *S. senftenberg* and the infection was rapidly shed by adult chickens.

Experimental efforts to produce chronic paratyphoid infections in both chicks and poults by oral administration of the organisms often result in the production of a disease of a transitory nature. During and a few weeks following the acute phase of the infection both tissues and intestinal cultures may readily yield positive isolations of the organisms administered. However, 1 or 2 months following oral infection most birds will be culturally negative. These findings have been very adequately substantiated by the experimental studies of Pomeroy and Fenstermacher, 1939; Gibbons and Moore, 1946; Buxton and Gordon, 1947; Gauger and Greaves, 1947; Wilson, 1948; Milner and Shaffer, 1952; Adler *et al.*, 1953; and Sieburth, 1957a. In actual field cases, the course of the disease may be longer than would be expected under controlled, experimental conditions.

Mortality from paratyphoid infection under natural conditions varies depending upon the environment, strain of infecting organism, and the presence of concurrent infections. Schalm (1937) in studies of *S. typhi-murium* infection in chicks found a great contrast in the low mortality among chicks kept on the farm where hatched, in comparison to the high mortality among chicks sold to others and transported to new quarters. Sieburth and Johnson (1956) found that the bluecomb agent, when administered to susceptible chicks in conjunction with *S. typhi-murium*, increased the mortality rate from 29 to 67 per cent. Biddle and Cover (1957) reported the isolation of Salmonella organisms from the respiratory tracts of chickens, some of which were infected with chronic respiratory disease.

HOST DISTRIBUTION

Paratyphoid infections occur in most species of warm- and cold-blooded animals. The organisms seldom exhibit host specificity. The frequent occurrence of *S. typhi-murium* var. *copenhagen* in pigeons is a notable exception. Buxton (1958), in discussing host specificity of Salmonella strains, called attention to the need for fundamental information on the chemical pathology of the reactions between the bacteria and host tissues. It was felt that such information would provide a means of explaining the carrier state in Salmonella infections. Edwards *et al.* (1948a) reported 111 serological types of Salmonella which were encountered in a total of 47 warm- and cold-blooded animal species.

Among domestic poultry, paratyphoid infections are most frequently encountered in turkeys and chickens. Turkeys are especially susceptible to these infections. The incidence of paratyphoid in chickens has revealed an increase during recent years as evidenced by the reports of Burr *et al.* (1957), Angstrom (1957), and Sieburth (1957a).

Pfaff (1921) was the first to report on the occurrence of paratyphoid infection in turkeys. Rettger *et al.* (1933) described the disease in young poults in the United States. Lee *et al.* (1936) encountered an acute disease that caused 90 per cent mortality among poults less than 5 weeks of age. In other flocks the losses were less, ranging from 40 to 70 per cent. The organism recovered from the poults was found to be pathogenic for chicks, poults, guinea pigs, and rabbits.

Cherrington *et al.* (1937) found *S. typhi-murium* to be responsible for the loss of many poults on several turkey ranches in Idaho. The mortality was as high as 60 per cent during the first week of brooding. Pomeroy and Fenstermacher (1939) first observed this infection in turkeys in Minnesota in 1932 when four poults were

gated had occurred in the southern part of New Jersey as had those reported previously by Moore and Mohler.

Lahaye and Willems (1927) considered paratyphoid to be one of the most important diseases of pigeons in Belgium. Khalifa (1935) investigated an epizootic among pigeons in Cairo, Egypt, which was due to *S. typhi-murium*. Jungherr and Wilcox (1934) reported a variant of *S. typhi-murium* recovered from spontaneously infected squabs. Morcos (1935) studied an outbreak among pigeons in various lofts in Cairo. The organism isolated closely resembled *S. anatum*. Adult fowl and sparrows were found to be quite refractive to the isolated culture. Edwards (1935) reported the close association of *S. typhi-murium* var. *copenhagen* with pigeons. Hoffmann and Edwards (1937) isolated paratyphoid organisms from pigeons which were believed to have transmitted the infection to rabbits on the same premises. Shirlaw and Iyer (1937) encountered an unusual loss among pigeons that were being used in the production of fowl pox vaccine. The organism isolated was *S. enteritidis*. Niemeyer (1939) recovered an organism from pigeons that was identified as *S typhi-murium*. The organism was recovered from 3 of 14 pigeons examined.

Gauger *et al.* (1940) published a comprehensive study of pigeon paratyphoid. The etiological type was *S. typhi-murium* var. *copenhagen*. These authors listed 26 references to paratyphoid epizootics in pigeons. Edwards *et al.* (1948c) found that 97.5 per cent of all cultures of *S. typhi-murium* isolated from pigeons were *S. typhi-murium* var. *copenhagen*. Moran (1961b) reported a similar high incidence of this variety in pigeons. This organism, unlike typical *S. typhi-murium* strains, lacks the somatic antigen 5. It is a unique example of a paratyphoid type exhibiting host specificity, and has resulted in most investigators suspecting direct or indirect association with pigeons as the source of infection when this type is encountered in other species of animals. Van Dorssen (1955) reported a serological

and cultural study of 223 *S. typhi-murium* strains isolated from pigeons in the Netherlands. He concluded that there does not exist any specific pigeon type of this organism as has been reported by some workers. Pigeons surviving paratyphoid outbreaks often become chronic carriers, excreting the organisms intermittently in their feces. Epizootics may occur among adult flocks, especially if their resistance is lowered by other conditions.

Edwards *et al.* (1948c) reported 10 serological types of Salmonella isolated from pheasants. *S. bredeney* was recovered from 7 outbreaks.

Graham (1936) studied an outbreak of paratyphoid among quail in which *S. oranienburg* was found to be the causative organism. Cunningham (1941) encountered an acute paratyphoid infection among quail chicks in which the heaviest mortality occurred in chicks from 3 to 9 days old. *S. bredeney* was isolated as the causative organism.

Hinshaw *et al.* (1942) isolated *S. bredeney* and *S. typhi-murium* from a group of chukar chicks. This report clearly indicated the isolation of multiple Salmonella types from a single outbreak wherein a 48.2 per cent mortality occurred among a group of 1,061 chicks. Francis *et al.* (1960) reported the isolation of *S. derby* and *S. anatum* from chukar partridges.

Beaudette and Edwards (1926) investigated paratyphoid in canaries and parrots. In one bird store, 200 birds of all ages became infected. The mortality was 35 per cent. *S. typhi-murium* was found to be the causative organism. Emmel and Stafseth (1929) reported several outbreaks of an epizootic of paratyphoid that occurred in canary bird stores throughout the state of Michigan. The disease was highly infectious, and the mortality was high. The incubation period was 4 or 5 days and the course of the disease varied from 2 to 4 days. *S. typhi-murium* was isolated from the internal organs.

Beaudette (1926a) reported that *S. typhi-murium* readily infected parrots as well as canaries. No differentiation could

be made between the strains of *S. typhimurium* isolated from the parrots and those previously isolated from canaries. Meyer and Eddie (1934, 1939) reported the isolation of Salmonella organisms from tropical psittacine birds including parrots, parrotlets, paroquets, and conures. Altman (1940) studied an outbreak of paratyphoid among a group of 170 canaries of all ages. The incidence of infection and mortality was greater in the young birds. Approximately 60 per cent of the infected birds died. *S. cholerae suis* was isolated as the etiological agent. Keymer (1959) reported that heavy losses occur in canaries and other passerine birds from *S. typhimurium* infection.

Meyer (1912), Buxton (1957a), and Kaye *et al.* (1961) have reported on the isolation of Salmonella organisms from budgerigars (parakeets). Meyer (1912) demonstrated that 37 per cent of parakeets from a single dealer were infected with *S. typhimurium*. Burkhart *et al.* (1962) experimentally infected parakeets and canaries with *S. typhimurium* and *S. heidelberg*. Stone (1960) cited Salmonella as an infectious cause of gastroenteritis in parakeets as encountered in veterinary practice.

Buxton (1957a) reported the isolation of *S. panama*, *S. paratyphi B*, and *S. typhi* from sea birds. Brest Nielsen (1960) isolated *S. typhimurium* from seagulls in Denmark, and Williams and Dodson (1960) reported the isolation of 3 Salmonella types from gulls. Salisbury (1958) reported that from 1948 to 1957 *S. typhimurium* was isolated from a seagull, mallard duck, pigeon, parakeet, goose, and pheasant as well as other species of poultry in New Zealand. Strauss *et al.* (1957) isolated *S. typhimurium* from the black-headed gull.

Sieburth (1958a) was unable to isolate any Salmonella organisms from the livers or intestines of 17 penguins cultured during a survey in the antarctic region. A history of salmonellosis was suggested in the ringed penguin, skua gull, and 2 sheath bills by serological tests.

Hudson (1942) encountered an outbreak of paratyphoid infection among a flock of

guinea fowl with a reported loss of 60 birds during a period of 6 weeks. *S. bredeney* was isolated from the infra-orbital sinuses.

Manninger (1913) examined the intestinal flora of various birds. From three birds belonging to the family of finches, he recovered *S. paratyphi B*. Keymer (1959) reported that he has observed *S. typhimurium* infection in the gouldian finch, the black-crested finch, the cordon bleu, the cut-throat, and the domestic variety of the Bengalese finch. Gordon and Buxton (1946) reported the isolation of paratyphoid organisms from a sparrow, Deom (1960) isolated a strain of *S. california* from a sparrow for the first time in the Congo. Dôzsa (1961) reported the isolation of *S. typhimurium* from the intestinal tract of 52 out of a total of 266 captured sparrows in Budapest. Edwards *et al.* (1948c) reported the isolation of paratyphoids from the following avian species not mentioned above: a peafowl, partridges, Japanese robins, a secretary bird, a diamond dove, a yellow-winged sugar bird, and callistes. Moran (1961b) reported the isolation of *S. typhimurium* from the following types of "other birds": cockatoo, hoatzin, hornbill, and parrot.

Cope *et al.* (1955) in a study of Salmonella in animals, birds, and reptiles isolated 8 types of paratyphoid organisms from a total of 20 species of fowl maintained in the Detroit Zoological Park. Csiszár *et al.* (1961) studied salmonellosis among birds of a zoological garden and found that approximately 27 per cent of the infected birds exhibited gastroenteritis. Such infections were not deemed to constitute a hazard to zoo visitors, but the danger for attendant personnel was stressed. Bigland *et al.* (1962), following a typing survey in Alberta, Canada, extending for 12 years, expressed the opinion that Salmonella organisms are seldom found in free-living wild birds and animals.

Hudson and Tudor (1957) isolated *S. typhimurium* from several varieties of free-flying birds including starlings, sparrows, rusty blackbirds, and a cowbird originating from 4 outbreaks in 3 areas of

north central New Jersey during a period of 2 years. They called attention to the possibility that these birds may spread the infection to man and domestic animals. Vallée et al. (1959) reported the isolation of *S. johannesburg* from Bengali birds during an enzootic in a commercial bird shop. No treatment was found effective. Petzelt and Steiniger (1961) isolated 18 types of Salmonella from chaffinches, house sparrows, black-headed gulls, starlings, and blackbirds captured in the area of a sewage purification plant of a big city.

The reader seeking additional historical information on paratyphoid outbreaks in various species of fowl is referred to the comprehensive review of Henning (1939).

Unlike the causative organisms of pullorum disease and fowl typhoid, the paratyphoids are common pathogens of most species of domestic and wild mammals and man. Cattle, swine, sheep, goats, dogs, cats, horses, mink, and foxes are among the many animal species that may be chronically infected and shed the organisms in large numbers in their feces. In these animals, paratyphoid usually occurs as an acute disease only in the very young or in old, debilitated animals under extreme conditions of stress. A voluminous amount of literature has been accumulated on Salmonella infections of animals other than poultry and for a review of this subject the reader is referred to Buxton (1957a).

Craige (1944), Wolff et al. (1948), Adler et al. (1951), Galton et al. (1952), Stucker et al. (1952), McElrath et al. (1952), and Mackel et al. (1952), have reported studies of paratyphoid isolations from the feces of dogs. Dogs and cats often carry Salmonella organisms in their digestive tract without showing any clinical symptoms. Bruner and Moran (1949) reported 26 Salmonella types recovered from dogs. Approximately 40 per cent of the cultures were *S. typhi-murium.* Thirty-four cultures isolated from cats included 17 types of Salmonella. Jungerman and Grumbles (1960) isolated Salmonella organisms from 9 of 100 mature healthy dogs

studied. Two of the dogs were infected with more than one Salmonella type. The infection was of a transient nature and cultures were negative 6 weeks later.

Rats and mice are frequently intestinal carriers of paratyphoid organisms, particularly *S. typhi-murium* and *S. enteritidis.* When *S. enteritidis* is encountered in poultry it is logical to suspect these rodents as a possible source of the infection. Salmonella have also been isolated from various insects including flies, fleas, and cockroaches. It is known that *S. enteritidis* can be transmitted through the complete life cycle of flies and that the infection may continue as long as 4 weeks within flies (Ostrolenk and Welch, 1942; Greenberg, 1959). Kaye et al. (1961) noted paratyphoid isolations from the housefly, tick, louse, flea, and cockroach. Trawiński and Trawińska (1960) were able to isolate Salmonella from artificially infected houseflies, their larvae and pupae. Buxton (1957a) cited references indicating that ticks may remain carriers for more than 30 days after oral infection.

McNeil and Hinshaw (1946) isolated *S. san-diego* and *S. newport* from Galapagos turtles, *S montevideo* from a Gila monster, and *S. manhattan* from an iguana. Hinshaw and McNeil (1945) examined 41 snakes caught on ranches in 7 localities in California. Eleven of the snakes yielded Salmonella on culture. Bövre and Sandbu (1959) isolated 19 types of Salmonella from 27 tortoises in Oslo.

Most of the Salmonella types recovered from poultry have also been found to infect man causing gastroenteritis or occasionally a more serious septicemic type infection. The role of eggs and poultry products in the transmission of Salmonella infections to man has been reviewed by Galton (1956), McCullough (1958), and Galton and Arnstein (1960).

Hinshaw et al. (1944) recorded the transmission of 2 types of paratyphoids (*S panama* and *S. montevideo*) to man believed to have occurred as a result of handling infected poults. Kaye et al. (1961) described a case of *S. typhi-murium* infec-

tion in an infant who was allowed to crawl in the droppings of a pet parakeet that was infected. Hinshaw and McNeil (1918, 1951) recorded 7 cases of gastroenteritis among poultry caretakers resulting from contact with acute outbreaks of pacatyphoid in fowl. Darby and Stafseth (1942) reviewed the literature with reference to 35 types of the genus *Salmonella* found in poultry in the United States. Most of these types have also been incriminated in pathological conditions in man. Cherry et al. (1946) isolated a nonmotile Salmonella from frozen turkeys. Browne (1919) was able to isolate Salmonella from the skin of turkeys that had been frozen for 13 months. Schneider and Gunderson (1919) recovered 4 Salmonella types from the skin of 4.4 per cent of 1,014 eviscerated chickens. Felsenfeld (1919) reported a case of human infection with *S. cubana* from eating a New York dressed chicken infected with this organism.

Felsenfeld et al. (1950) in a survey of Salmonella organisms in market meat, eggs, and milk called attention to the need for proper inspection of certain foods intended for human consumption. Brandly (1951) and Dolman (1954) have also emphasized the public health significance of Salmonella infections of poultry. Abelseth and Robertson (1953) implicated *S. typhimurium* infection of turkeys as a definite public health hazard. Anderson et al. (1955) reported several cases of *S. typhimurium* infection in children with a likely source of the infection being Easter chicks. *S. typhi-murium* was recovered from the stools of the children and also the chicks.

Gunderson et al. (1954) and Galton et al. (1955) have discussed the occurrence and distribution of paratyphoid organisms in poultry processing plants. Florin and Nilsson (1959) cited the very important influence of techniques in slaughter on the contamination of carcasses in the case of intestinal salmonellosis of poultry. Recognizing this fact, many poultry processing plants in the United States are establishing laboratory control testing services to monitor the presence of Salmonella organisms in their operations. If results warrant, necessary measures are taken to improve sanitary conditions within the plant.

Savage (1956) noted that the incidence of Salmonella food poisoning in Great Britain was increasing. Meat and egg products were cited as the chief sources of the infection in man. Canale-Parola and Ordal (1957) found 5 out of 40 poultry pies sampled to contain Salmonella organisms. They recommended that manufacturers pled technology and sanitary procedures used in preparing the pies and give longer baking periods. Similar studies have been reported by Litsky et al. (1957). Beloian and Schlosser (1963) reported that baked foods that reach a temperature of 71° C. (160° F.) or higher in the slowest heating region can be considered safe from any Salmonella organisms that may be present in the ingredients.

Edwards (1958) in an excellent review emphasized the importance of poultry, and animal species in general, in the transmission of salmonellosis to man. Brobst et al. (1958) were successful in isolating Salmonella from chickens and ducks being prepared for market as well as from vats in poultry processing plants in Western Pennsylvania. They concluded that potentially these Salmonella are a serious menace to those who handle the birds and to the families that may receive them. Van Keulen (1959) described the role played by animal-borne salmonellosis in human infections. Attention was drawn to the significance of infection through the medium of foodstuffs of poultry and animal origin, whether primarily or secondarily infected. Better hygiene in the production and handling of foodstuffs of animal origin was stressed. Mackel et al. (1959) studied an outbreak of human gastroenteritis due to *S. typhi-murium* among 300 inmates of a penal institution. The patients had eaten roasted turkey which had been sliced on the same chopping block on which the uncooked fowl had been prepared. Those persons eating only reheated meat did not become ill. *S. typhi-murium* was recovered from

more than 100 persons that had eaten the meat as well as from turkey necks that had been frozen. Spink (1960) traced an outbreak of *S. thompson* infection involving 35 people in Great Britain to a broiler shop. The organism was isolated from cooked chicken, the manager of the shop, his assistant, and from living broilers at a packing station supplying the shop.

Walker (1960) called attention to the increased incidence of salmonellosis in humans in Great Britain, and cautioned that the use of antibiotics in broiler rations is resulting in the emergence of resistant Salmonella strains. Such strains may cause an increase in the carrier rate and may multiply more rapidly in contaminated carcasses. It has been suggested (Anon., 1961) that the carcasses of poultry for the market may be immersed in slush ice containing 10 p.p.m. of chlortetracycline for 2 hours to inhibit the growth of Salmonella. Attention is called to the development of chlortetracycline-resistant strains of Salmonella as this drug may be given to the birds as a feed additive. Garside *et al.* (1960) reported that birds receiving antibiotics for the prevention or treatment of Salmonella infections may be a public health hazard because of the large number of infected carrier birds remaining in such flocks.

Morris and Ayres (1960) found that 0 to 9 per cent of the samples obtained from turkey processing plants and 7 to 14 per cent of the samples from chicken processing plants were positive on culture for Salmonella. Specimens were taken from 10 sampling stations including the scald tanks, carcass surfaces, and final rinse water. Twenty-eight Salmonella cultures were isolated from chickens and 12 from turkeys. Tailyour and Avery (1960) cultured the viscera and intestinal contents of 525 market weight turkeys in Vancouver, British Columbia, for Salmonella. Four birds (0.76 per cent) were found to be harboring *S. derby*. Wilson *et al.* (1961) found approximately 17 per cent of 525 raw poultry specimens in the Cincinnati area contaminated with Salmonella. Eighteen serotypes were encountered during the study

and Salmonella isolations showed an increasing trend from supermarket through general store, meat market, and poultry market. Eight per cent of household turkey specimens were positive for Salmonella.

Edwards (1958) and Quist (1962) reported a 7-fold increase of Salmonella infections other than typhoid fever in humans in the United States from 1949-1960 and noted that Salmonella infections in poultry constitute the major source of human disease. Sadler *et al.* (1961) random-sampled market meat birds for Salmonella organisms. Infected or carrier birds were found being processed on 43 per cent of the sampling days for turkeys, 26 per cent for chicken fryers, and 12 per cent for hens. Dixon and Pooley (1961) isolated Salmonella organisms from 15.8 per cent of 544 specimens taken at a poultry plant in Great Britain.

Raw, frozen, or dried eggs are rather frequently implicated in Salmonella infections in man. An outbreak due to raw eggs containing *S. tennessee* was reported by Watt (1945). Blaxland and Blowers (1951) implicated *S. typhi-murium* in duck eggs as a cause of human food infection. Such occurrences have been frequently reported in Europe.

The occurrence of Salmonella in egg powder has been extensively studied by Schneider (1946) and Solowey *et al.* (1946, 1947). McCullough and Eisele (1951a, b, c, d), in detailed clinical studies of experimental salmonellosis in human volunteers, were able to establish the pathogenicity of 6 Salmonella types which had been isolated from spray-dried whole egg powder. Cultures were administered in graduated doses in eggnogs and the following Salmonella types were used in these studies: *S. meleagridis, S. anatum, S. newport, S. derby, S. bareilly,* and *S. pullorum.*

Alves de Oliveira and Gomes (1954) described a hospital epidemic of *S. typhi-murium* infection involving 200 persons and resulting in 3 deaths. The outbreak was traced to eggs consumed in the diet. Newell *et al.* (1955) traced 2 outbreaks of

paratyphoid fever (*S. paratyphi B*) in humans to the consumption of cream-filled cakes. The same phage type of *S. paratyphi B* was found in unopened cans of Chinese frozen whole egg used by the bakeries, in some members of the staff, and in the patients. An anonymous report (1956) disclosed that in 1955 in Great Britain, there was an increase of 49 per cent in food poisoning, due principally to Salmonella infections frequently traced to egg products. Buxton (1957b) called attention to the fact that human foods composed of eggs and egg products are a common source of Salmonella food infection in man. It was emphasized that the rate of infection is much higher among eggs with cracked and fecal-contaminated shells than among those laid under clean, hygienic conditions.

McCullough (1958) discussed the importance of poultry and poultry products, especially eggs, in the epidemiology of salmonellosis in humans in the United States. In one epidemiological investigation, *S. infantis* was isolated from poultry feedstuffs, eggs, and patients that had eaten lightly cooked and uncooked egg products (Newell *et al.*, 1959). Taylor (1960) called attention to the importance of eggs and egg products in the transmission of Salmonella infections in man. It was noted that the infection is more often traced to frozen eggs, dried eggs, and other egg products.

Philbrook *et al.* (1960) reported an outbreak of *S. typhi-murium* food poisoning traced to infected chicken eggs consumed in eggnogs by patients at an institution in Massachusetts. Eggnogs consumed in the institution are now pasteurized. Fey and Wiesmann (1960) described a family outbreak of salmonellosis in Switzerland caused by imported egg powder which contained 5 different Salmonella types. Attention has been called (Anon., 1961) to the public health significance of Salmonella in poultry and the fact that eggs that may be contaminated with Salmonella should be cooked well. Hobbs (1961) referred to the importance of poultry products in transmitting salmonellosis to humans, and listed pasteurization of egg products and

the pelleting of animal feeds as factors that would help to reduce this transmission. Thatcher and Montford (1962) reported that 14 different Salmonella types were isolated from 119 egg-containing cake mixes of which 65 contained Salmonella. The importance of breaking the animal-to-animal chain of infection in the control of salmonellosis was emphasized. Taylor (1963) has reviewed the Salmonella serotypes isolated from egg products and found in human infections in the United Kingdom. During a hospital-associated epidemic of *S. derby* infection (Anon., 1963a) in the United States it was recommended that cracked and unclean eggs should not be used. It was further suggested that commercial products containing eggs or egg products should be cooked well.

MODES OF TRANSMISSION

The wide distribution of paratyphoid organisms under natural conditions contributes materially to their rapid spread. Preventive efforts to be successful must give first consideration to the means by which the disease is transmitted. The frequent isolation of paratyphoid organisms from eggs has resulted in the reference to the disease as an egg-borne infection. However, in consideration of the spread of paratyphoid infections through the medium of the egg, it is important that a distinction be drawn between direct ovarian transmission and transmission through shell penetration.

Numerous investigators (Dalling and Warrack, 1932; McGaughey, 1932; Warrack and Dalling, 1933; Wilson, 1945; Karlshøj and Szabo, 1949) have recovered paratyphoid organisms from the yolk of duck eggs, providing ample evidence that direct ovarian transmission is quite common in this species. Hole (1932) and Clarenburg (1939) have also presented definite evidence that duck eggs may be infected as a result of localization of the organism in the ovary.

Paratyphoid infections of turkeys may occasionally be directly transmitted through the ovaries. However, experimen-

tal evidence does not indicate that infected turkeys produce a high percentage of infected eggs. Cherrington et al. (1937) reported the isolation of S. typhi-murium from the ovaries of two turkeys. The results of these investigations indicated that the infection was transmitted from the ovaries of the breeding hens to fertile eggs. Lee et al. (1936) investigated the direct ovarian transmission of S. typhi-murium infection of turkeys and were able to recover the organism from the ovarian tissues of infected hens. Pomeroy and Fenstermacher (1939) reported the isolation of S. typhi-murium from the ovary and oviduct of 3 of 10 naturally infected turkeys. Hinshaw and McNeil (1913a) were able to isolate S. typhi-murium from the ovaries and oviducts of turkeys. Gauger and Greaves (1946a) isolated S. typhi-murium from the ovary of a turkey hen. Due to the very short incubation period that was encountered in a natural outbreak of S. reading infection in poults, Mitrovic (1956) suggested the likelihood of direct egg transmission. Yamamoto et al. (1961a) reported the isolation of S. typhi-murium from the ovaries of an adult turkey that was experimentally infected.

There is little evidence in the literature to suggest that direct ovarian transmission is a common occurrence in chickens. Wilson (1950) reported the isolation of S. typhi murium from chicken eggs, and suggested the possibility of direct ovarian transmission. Clarenburg and Romijn (1954) were successful on one occasion in isolating S. bareilly from the ovary of an infected chicken. Others have made similar reports; however, isolations of paratyphoid organisms from ovarian tissues of chickens are not common. Wilson (1948) stated that "it seems certain that direct egg transmission of infection rarely, if ever, occurs in chicks as most workers have consistently failed to isolate the organism in the content of chicken eggs." This is in direct contrast to the cycle of pullorum disease in chickens. Mundt and Tugwell (1958) were unable to recover Salmonella organisms from the contents of eggs laid by White Leghorn pullets experimentally infected orally and intravenously with various types of paratyphoid organisms. However, the organisms were recovered from shells of eggs laid by the most severely infected group 21 days after infection and from feces 35 days after infection. Snyser and Van Roekel (1959) cultured eggs of reacting chickens from a flock known to be infected with S. typhi-murium. The organism was isolated from the eggs on one occasion.

Fecal contamination of eggshells with paratyphoid organisms during the process of laying or from contaminated nests or incubators after laying is of foremost importance in the spread of the disease. Intestinal carriers of the organisms are common (Emmel, 1936a; Mallmann et al., 1942; Posell, 1942; Hinshaw and McNeil, 1913a; Gauger and Greaves, 1916c, 1917; Gibbons and Moore, 1916; Chase, 1917; Milner and Shaffer, 1952; Adler et al., 1953; Sieburth, 1957a). Buxton and Gordon (1917) demonstrated that chickens may remain intestinal carriers of S. thompson up to 14 months. Yamamoto et al. (1961a) inoculated S. typhi-murium into the crop of adult turkeys and found that the organisms were generally shed in higher numbers in the cecal than in the other intestinal feces. Cloacal swabs were positive (83.4 per cent) at 14 days and also (27.8 per cent) at autopsy 35 to 44 days postinoculation. Total positive isolations were increased to 67 per cent when all methods of culture (swab, direct fecal, and visceral organs) were considered.

Perek and Rabinovitz (1957) were able to obtain positive fecal cultures of S. enteritidis for a period of 3 months from a naturally infected adult flock of geese. After 7 months, fecal cultures were negative. Bacteriological examination of all internal organs was also negative at that time. Pulst (1960) found that geese infected orally with S. typhi-murium excreted the organism for 18–26 days after infection, and one goose became a chronic carrier. All of the birds developed agglutinin titers which disappeared in about 4 weeks.

Schalm (1937) was able to demonstrate that *S. typhi-murium* in fecal material smeared on the surface of chicken eggs was capable of penetrating the shell and multiplying within the egg. These findings suggested a means by which paratyphoid organisms might be introduced into the incubator by contaminated eggs with subsequent spread to the hatched chicks or poults. Maclaury and Moran (1959) found that freshly laid eggs, cooling in contact with contaminating organisms, will draw the organisms through the shell pores. The bacteria may be recovered on the day of contamination from the inside of the shells of 84 to 95 per cent of the eggs. Beach (1936) also called attention to the role of contamination on the eggshell in the transmission of the infection. Buxton and Gordon (1947) noted that the average diameter of the pores of chicken eggs varied from 6 to 13 micra, which would readily permit paratyphoid organisms to penetrate the shell when conditions are favorable.

Wright and Frank (1956) demonstrated that a few eggs are penetrated by *S. typhi-murium* on the first day and the great majority by the end of the seventh day. They also found that the specific gravity of the eggs was related to shell thickness, and there was an increase in the proportion of eggs penetrated in the low specific gravity groups. Beattie (1960) found that embryonic infection with *S. thompson* was highest during those months of the year when environmental temperatures are lowest, indicating a rapid shell penetration.

Pomeroy and Fenstermacher (1939) incubated 325 eggs from turkeys that had shown positive agglutination reactions to one or more paratyphoid antigens. Ninety of the eggs were infertile, 103 contained dead embryos, 7 contained poults which had pipped the shells but failed to hatch, and 115 hatched. On bacteriological examination *S. typhi-murium* was recovered from 3 infertile eggs (3.33 per cent), from 8 eggs containing dead embryos, and from 1 egg containing a dead poult. In further studies Pomeroy and Fenstermacher (1941) found that *S. typhi-murium* organisms,

when mixed with sterile turkey feces and smeared on one-third of the surface of turkey eggs, were able to penetrate the eggshell during incubation and invade the egg contents. In one group 17.6 per cent, and in a second group 16.0 per cent of the eggshells were penetrated.

Gauger and Greaves (1946a) examined the contents of eggs from turkeys naturally and artificially infected with *S. typhi-murium*. The organism was not recovered from the contents of 164 eggs laid by 6 naturally infected carrier hens although these birds had voided *S. typhi-murium* in their feces quite regularly during the period of the experimental study. Thirty-four of the eggs cultured were laid by one bird found to have *S. typhi-murium* ovarian infection. *S. typhi-murium* was recovered from the shell of 27 eggs and shell and contents of 6 of 117 eggs laid by a group of turkeys experimentally infected with *S. typhi-murium*. These studies provided additional evidence of the importance of shell contamination in the transmission cycle of paratyphoid infections. Yamamoto *et al.* (1961a) found that *S. typhi-murium* could be recovered from the surface of eggs laid by experimentally infected adult turkeys; however, subsequent culture of the contents of incubated eggs yielded negative results.

Wilson (1945) isolated *S. typhi-murium* and *S. thompson* from the outside of eggshells and suggested that the mixing of such eggs with clean eggs is a means of spreading the infection in the incubator. Buxton and Gordon (1947) demonstrated that *S. thompson* could readily penetrate the shell of chicken eggs stored at 37° C., but penetration was less common in eggs stored at room temperature. Gregory (1948) reported the penetration of *S. typhi-murium* and *S. bredeney* through the shell of chicken and turkey eggs under different conditions of humidity.

Cantor and McFarlane (1948) isolated strains of *S. montevideo* and *S. anatum* from 13 (0.6 per cent) of 2,132 samples of eggshell scrapings. Wilson (1948) reported the examination of 1,023 chicken

eggs, from 60 of which S. thompson was isolated. Forty-five of the eggs yielded the organism from the outside of the shell and 17 from the contents. It was felt that penetration of the shell readily occurred as the eggs were stored for a period of 14 days and no effort was made to keep the various eggs apart. Watanabe et al. (1958) were unable to isolate S. senftenberg from the eggs of adult hens that were artificially infected with the organism and reacted positively to both somatic and flagellar antigens of S. senftenberg. These workers were able, however, to isolate S. senftenberg from the shell membranes of dead embryonated eggs, suggesting that these organisms may invade the shell during incubation. Clarenburg and Romijn (1951) cultured 160 eggs which were placed in an incubator after having been contaminated with a mixture of chicken feces and broth cultures of S. bareilly. Eggs were cultured daily, but in no case could Salmonella be recovered from either the eggs or the embryos. Stokes et al. (1956) demonstrated that paratyphoid organisms are able to penetrate the eggshell membrane and contaminate the yolk if a temperature favorable to the growth of the bacteria is maintained.

Temperature and moisture play a very important part in the rate of penetration of the eggshell by paratyphoids. Schaaf (1936) found that in the case of duck eggs penetration occurred in 5 days while Lerche (1956) reported that at room temperature penetration required 15 days. Gaugusch (1958) artificially infected the surface of duck eggs with Salmonella and found that the organisms had penetrated to the interior of the eggs within 16–24 days following the infection. Formaldehyde fumigation was found to be very effective in the disinfection of infected eggs. Wilson (1948) demonstrated that the virulence of the organism is important in the rate of eggshell penetration. He found that after repeated passage, penetration of the shell could occur in 3 days. Bigland and Papas (1953) found shell penetration in 8 per cent of eggs contaminated

with S. typhi-murium, 3 per cent contaminated with S. oranienburg, and 16 per cent with S. kentucky. No penetration was found when S. bareilly was used. Ellemann (1959) found that S. typhi-murium did not penetrate the shells of eggs stored for more than 2 months at 4° C. However, penetration was demonstrated as early as 4 days when eggs were stored at 30° C. It was further noted that storage of eggs is most favorable in a cold room with a low relative humidity.

Experimental evidence indicates that penetration of the shell occurs during the first week of incubation, and to a much lesser degree in eggs stored in a cool environment. This is an important consideration in the prevention of paratyphoid infections, and will be discussed in more detail under the section on Prevention and Control.

Organisms that have gained entrance into the egg are able to multiply rapidly in the yolk and subsequently infect the developing embryo which may die or hatch to serve as a source of the infection for other young birds. Egg albumen has very little inhibitory effect on Salmonella organisms that penetrate the shell (Burton and Gordon, 1917; Gregory, 1948; Lancaster and Crabb, 1953a).

Contaminated eggshells and other debris of the hatch may also serve as a source of the infection in the incubator. From the incubator the organisms may be distributed by air currents throughout the hatchery and a high level of Salmonella aerosol infection established. Samples of air taken within the hatchery may remain positive for several weeks or months, and the infection spreads to subsequent hatches through this means. Contaminated down and dust may carry the organisms and be inhaled by susceptible young birds. Adler et al. (1953) demonstrated that poults could be infected with S. typhi-murium by the intranasal route.

Paratyphoid infection, when established in the brooder, is rapidly transmitted by inhalation, fecal contamination of feed and water, or direct consumption of fecal

ples of complete poultry feeds examined, 8 per cent yielded Salmonella. It appeared probable that the organisms were present in relatively small numbers in contaminated material, although it was stressed that multiplication may occur in mashes under suitable conditions of moisture and temperature. Graham-Jones and Fiennes (1959) isolated a Salmonella from 2 African-Grey parrots which excreted abnormally green feces. The authors were able to isolate the same Salmonella type from egg yolk material of Chinese origin included in the parrots' seed. They questioned the desirability of including such egg products in the seed of any grain-eating birds. Moran (1960) called attention to the fact that in 1957 only 60 Salmonella cultures from feed products of animal origin were typed; however, in 1958, 555 cultures of the same origin were received for typing. This sharp increase was interpreted to reflect the interest in the occurrence of Salmonella in feed products. She indicated that control of salmonellosis can begin only after strict standards of sanitation, rigidly enforced, are applied to production of animal feed ingredients.

Bischoff (1960) reviewed the world-wide distribution of 113 Salmonella types isolated from egg products and animal feeds. Strict bacteriological screening of all imported products for Salmonella organisms was emphasized. Hofmann et al. (1960) cultured duck feathers imported into Austria. Fifteen Salmonella serotypes were isolated from feathers imported from Asia; however, none was isolated from those imported from European countries or the United States. Also, the dust produced during feather cleaning contained Salmonella, but none could be isolated from the finished goods leaving the factory. As the dust is often used without heating in fertilizers, the danger of infection through this route was stressed. Schwerin (1960) reported the isolation of S. newington from gulls' droppings near a fish meal factory in which samples of fish meal occasionally yielded S newington in spite of strict hygienic measures. Taylor (1960) noted that it is both possible and practical to treat animal feed and feed constituents with heat to destroy Salmonella which they may contain. Such a practice was cited as having a potentially profound effect on the general incidence of Salmonella infections. Pelleting of poultry feeds has been suggested as an effective measure to destroy Salmonella organisms that may be present (Hobbs, 1961).

Quesada et al. (1960) found that fish meal imported into Italy from Angola was contaminated with S. binza, which was found to be pathogenic for chickens. Bischoff (1961) reported on the Salmonella types isolated from egg products and feeds of animal origin. A total of 115 Salmonella types were recovered, and the strict bacteriological control of imported products was emphasized. Giovaneli and Dominguez (1960) reported that hemp seed fed to flute canaries was the source of a natural outbreak of S. typhi-murium infection. The organism was isolated from cardiac blood and fecal material of the infected birds.

Morehouse and Wedman (1961) reported a survey of Salmonella and other disease-producing organisms in animal by-products. Egg products, poultry by-products, and meat scraps were among the feed constituents found to contain Salmonella. It was concluded that Salmonella organisms present in animal by-products and finished rations are a potential disease threat to poultry as well as other animal species. Wedman (1961) called attention to the potential disease problem resulting from the "cycling" of a number of Salmonella serotypes from farms to processing plants and back to farms by animal by-products incorporated into feeds. It was felt that realistic, workable measures to minimize the chance for exposure of poultry to Salmonella occurring in animal by-products and rations are desirable and essential. Niven (1961) pointed out some of the problems that industry encounters in efforts to eliminate Salmonella organisms from rendered animal by-products used in the manufac-

ture of animal feeds. The need for further information concerning the real significance of this problem to animal health was emphasized.

Pomcroy and Grady (1961) conducted bacteriological examinations of 980 samples of animal by-products used in manufacturing poultry feeds in 22 states and Canada. Salmonella was isolated from 175 of the samples and 43 serotypes were identified. Many of the same types have been isolated from poultry submitted to diagnostic laboratories. The authors pointed out that if continued progress is to be made in reducing the incidence of paratyphoid infections in poultry, every effort must be made to eliminate the contamination of feed ingredients with Salmonella. Thomas (1961) discussed the beneficial effects of legal measures that have been taken to restrict the use of Salmonella-contaminated ingredients in the production of animal feeds in Belgium. Hammer (1961) indicated that Salmonella infections of poultry can be traced back to the feed they receive and recommended that legal measures should be taken to minimize infection among all domestic animals through this route.

Grumbles and Flowers (1961) cultured for Salmonella 136 samples of cottonseed and/or soybean oil meal used in the preparation of poultry feeds. Six Salmonella types were isolated from 5.14 per cent of the samples. This study is especially significant since it demonstrates that Salmonella may also be present in feed constituents of vegetable origin. These authors stated that "a method of processing and handling poultry feed and feed ingredients to assure freedom from Salmonella contamination must be developed before a satisfactory control program for paratyphoid infections in turkeys can be carried out." Quist (1962) reported the isolation of 13 serotypes of Salmonella from 60 samples of protein supplement used in poultry feed manufacture. He also pointed out that two significant factors that have influenced the high rates of paratyphoid infec-

tion in poultry are infection through egg transmission and exposure of birds to feeds heavily contaminated with Salmonella organisms.

Boyer et al. (1962) described in detail two cases of salmonellosis in turkey poults and one case in chicks in which it was possible to correlate Salmonella serotypes causing the infections with those isolated from samples of feed that the birds were receiving. In two other cases the types of Salmonella isolated from the birds were not identified with the types recovered from the feed. It was emphasized that no control program for Salmonella infections in poultry will be of much value until a way can be found to keep these organisms out of the feed. Burr and Helmboldt (1962), during a one-year period, cultured 131 fish meal, 161 meat scrap, and 145 poultry by-products before incorporation into finished poultry feeds. Fifty-six Salmonella isolations were made from an average of 12.8 per cent of the samples, and 10 Salmonella types were represented. These workers called attention to cross reactions that can occur from such infections during pullorum-typhoid testing. Galbraith et al. (1962), in a survey of Salmonella organisms in pet foods and garden fertilizers in Great Britain, found 27 per cent of raw horse meat samples, 16 per cent of other raw meat, 12 per cent of prepared pet food, and 13 per cent of garden fertilizers to contain Salmonella organisms.

As Edwards (1958) has noted, it is obvious that in any effort to eradicate salmonellosis from domestic animals it is necessary to take into consideration the continuous seeding of the population through infected feedstuffs.

Rats and mice are frequent carriers of the organisms, and their droppings may readily contaminate feed supplies. Pigeons, sparrows, and various other species of wild birds may also serve as a source of the infection for domestic poultry flocks. Brest Nielsen (1960) has suggested that wild birds are a source of Salmonella infections in Danish poultry flocks. Gaugusch

and Malwińska (1956) recovered *S. typhi-murium* from natural water reservoirs on which various types of water birds lived and fed. They found such sampling of water to be an important supplementary method of diagnosis of salmonellosis in free-flying water birds.

Attention has already been drawn to dogs, cats, swine, cattle, sheep, and goats as sources of paratyphoid infections for poultry. Gwatkin and Mitchell (1911) and McNeil and Hinshaw (1911) have discussed the part that snakes, flies (*Musca domestica*), and cats may play in the transmission of the infections to poultry. Man must also be recognized as a possible source of the disease (Gordon and Buxton, 1916). This source may involve not only the caretakers but also waste products of human source. Hinshaw *et al.* (1944) record instances of humans transmitting the infection to poults. Poultry may serve as a source of salmonellosis for other animal species on the farm. Ladehoff (1959) cited evidence that *S. typhi-murium* infection in calves was introduced by apparently healthy geese and ducks.

Mortelmans *et al.* (1958) isolated 5 serotypes of Salmonella from chicks shipped into the Belgian Congo from other parts of Africa and Europe by air. They called attention to the importance of air shipments as a means of rapid spread of salmonellosis among poultry. Rao and Gupta (1961) also reported on the isolation of Salmonella from imported chickens in India.

In transmission among adult poultry the feces of infected carriers is probably the most common source of the organisms. The bacterial population and the nature of the environment are among the many factors that determine the extent of such transmission. Buxton and Gordon (1917) reported an instance in which *S. thompson* infected the gallbladder of a chicken, and the organisms were excreted in the feces for at least 18 months.

adults closely simulate those observed in pullorum disease, fowl typhoid, Arizona infections, and several other diseases. A differential diagnosis based on symptoms and necropsy findings is not possible.

Young birds. Basically paratyphoid infection is a disease of young fowl with environmental conditions, degree of exposure, and the presence of concurrent infections having an important influence on the severity of an outbreak. In acute outbreaks with deaths occurring in the incubator or during the first few days after hatching no symptoms may be noted. In such instances the infection is acquired by egg transmission or early incubator exposure. A high proportion of pipped and unpipped eggs containing dead embryos may be observed.

In experimental exposure studies of turkey poults orally administered broth cultures of *S. typhi-murium*, Pomeroy (1911) observed that losses started 2 to 3 days after exposure and discontinued by the time the poults were 2 weeks old. When symptoms are observed in young birds 1 week of age or older, contact exposure or an outside source of the disease should be considered.

Symptoms of paratyphoid infections in all species of young fowl are very similar and include the following signs: a progressive state of somnolence evident by a tendency to stand in one position with the head lowered, the eyes closed, the wings drooping, and the feathers ruffled; a marked anorexia and increased water consumption; a profuse, watery diarrhea with pasting of the vent and a tendency of the birds to huddle together near the source of heat. Bierer and Vickers (1960b) found that nitrofuran therapy of *S. typhi-murium* infection in poults reduced the incidence of soiled and pasted vents. Respiratory symptoms are not commonly observed. Clemmer *et al.* (1960) found that experimentally produced pulmonary infections in chicks were usually self-limited although 2–3 weeks may be required for autosterili-

condition in chicks which he was able to produce by parenteral inoculation of the endotoxin of *S. typhi-murium*. Rasmussen (1962) described the frequency with which *S. typhi-murium* is associated with arthritis in ducks. Lee *et al.* (1956) reported that chicks orally infected with *S. typhi-murium* died between the fifth and twelfth day, most losses occurring between the fifth and eighth day. Evans *et al.* (1955) have described blindness in chicks associated with salmonellosis. Lannek *et al.* (1962) reported conjunctivitis in natural *S. typhi-murium* infection in chicks. Salisbury (1958) found navel infection in young chicks from which *S. typhi-murium* was isolated. Bierer (1961) demonstrated that a navel route of infection was established by the incubator-spray inoculation of baby chicks with *S. typhi-murium*. The organism was also recovered from livers, unabsorbed yolks, and ceca of chicks so infected.

Dougherty (1953) and Price *et al.* (1962) found that ducklings infected with paratyphoid usually die slowly, tremble and gasp for air, and very often have pasted vents. The eyelids of ducklings frequently become swollen and edematous. Truscott (1956) reported that infected ducklings appeared drowsy and weak. Peick and Rabinovitz (1957) found that goslings with *Salmonella* infection were sluggish and refused feed or ate very little, but consumed large quantities of water. Diarrhea was observed in some birds.

Arthritis is commonly observed in paratyphoid infection of pigeons. It most frequently involves the wing joints and is evident as soft, subcutaneous swellings. Swelling of the eyelids is also a common symptom seen in pigeons. Das *et al.* (1959) reported that affected pigeons demonstrated anorexia, greenish diarrhea, drowsiness, and death within 2–3 days. Altman (1940) observed that infected canaries seemed to "puff up," developed convulsions, and died within 2 to 3 days. Consupation was observed in some cases; later, diarrhea developed. The droppings were greenish in color and, in some instances, bloody. Keymer (1959), in discussing paratyphoid infection in canaries and other passerine birds, noted that incubation takes 4 to 5 days, and the infection is usually acute. The birds will die 2 to 4 days after the plumage becomes ruffled, and greenish diarrhea is observed. Vent feathers usually become matted with droppings and convulsions often precede death. Surviving birds are apparently carriers and can infect susceptible birds.

Lesions in young birds may be entirely absent in extremely severe outbreaks. In outbreaks which permit the development of advanced cases, the following lesions are most commonly observed: emaciation, dehydration, coagulated yolks, congested liver and spleen with hemorrhagic streaks or pin-point, necrotic foci, congested kidneys, and pericarditis with adhesions. However, both heart and lung lesions are not as frequently observed as in pullorum disease. Hemorrhagic enteritis involving the duodenum is a common occurrence in poults. Cecal cores are occasionally observed. Ballantyne (1953) reported that in cases which he studied, caseous ceca were found in 33 per cent of poults infected with *S. oranienburg*, in 46 per cent of poults infected with *S. typhi-murium*, and in 20 per cent of poults with *S. newport*. The same condition occurred in 33 per cent of chicks with *S. typhi-murium* infection.

Lukas and Bradford (1954) in an effort to classify necropsy findings of paratyphoid outbreaks encountered among poults during a survey in California found: (1) systemic involvement with lesions such as pericarditis, necrotic foci in the liver and heart, air-sac involvement, central nervous system disturbance, and severe catarrhal enteritis with cecal cores (20.8 per cent of specimens); (2) uncomplicated catarrhal enteritis (33.2 per cent of specimens); (3) enteritis complicated with Coccidium, Hexamita, or sinusitis-air-sac infection (28.4 per cent of specimens); (4) other findings such as water starvation, ascites, mycosis, etc. (15 per cent of specimens); (5) no gross lesions (2.5 per cent of specimens). *S. typhi-murium* was most frequent-

ly involved in systemic cases, while other common types such as *S. anatum* and *S. manhattan* were more common in cases with uncomplicated diarrhea.

Truscott (1956), on necropsy of ducklings infected with *S. moscow*, found the livers of the birds bronze in color and covered with small grey areas of focal necrosis. The air sacs were somewhat opaque with yellow fibrinous plaques. Dougherty (1961) described in detail the pathology of *S. typhi-murium* and *S. enteritidis* infection in the White Pekin duckling. Gross enlargement of the liver with or without focal necrosis, formation of caseous plugs in the ceca, and enlargement and mottling of the rectum were the predominant lesions. Pericarditis, epicarditis, and myocarditis were found. Central nervous lesions consisted of thickened meninges in about one third of the typical salmonellosis cases confirmed by bacteriological studies. Price *et al.* (1962), in necropsy studies of ducklings infected with Salmonella, found necrotic foci in the liver, cheesy plugs in the ceca, impaction of the rectum, and blanching of the kidneys. Rasmussen (1962) described the pathology of arthritis in slaughter ducks due predominantly to *S. typhi-murium*. Among 827 arthritic ducks, *S. typhi-murium* was isolated from 12 per cent of the inflamed hock joints, 75 per cent of the knee joints, and 52 per cent of the hip joints. Perek and Rabinovitz (1957) found that at autopsy, goslings revealed pale flesh with some necrotic foci on the livers. Das *et al.* (1959) observed yellowish-green fibrinous deposits in the oral cavity and at the base of the tongue and on the upper palate of pigeons infected with *S. typhi-murium*.

Adult birds. Mature fowl generally exhibit no outward signs of the infection. Acute outbreaks in semimature and adult birds under natural conditions are rare. However, adults in infected flocks are often chronic carriers of paratyphoid organisms both in their internal organs and intestinal tracts. Wilson (1948) found that adult chickens may remain intestinal car-

riers of *S. typhi-murium* and *S. thompson* for periods up to 9 to 16 months.

Experimental paratyphoid infection of adult chickens and turkeys by either the parenteral or oral route of administration will result in an acute disease of short duration. Symptoms during the acute stage include loss of appetite, increased water consumption, diarrhea, dehydration, and general listlessness. Recovery is rapid in most cases, and death losses do not usually exceed 10 per cent.

Acutely infected adult fowl may reveal congested and swollen liver, spleen, and kidneys, hemorrhagic or necrotic enteritis, pericarditis, and peritonitis. Leg weakness in mature birds is not uncommon. Higgins *et al.* (1944) encountered a flock of 24-week-old turkeys infected with paratyphoid in which 10 per cent of the birds were so severely affected with an arthritic condition that they were unsuitable for marketing. Chaplin and Hamilton (1957) reported a synovitis in turkeys, similar to that ascribed to intravenous staphylococcal inoculation, following intravenous inoculation of broth cultures of *S. thompson*.

In an infected environment under natural conditions the disease is constantly transmitted among adults through consumption of the organisms; however, the period that the birds are infected may be transient. The degree to which adult chickens and turkeys become chronic carriers is dependent upon the number of organisms to which they are exposed, the virulence of the strains, and the general condition of the infected individuals.

Chronic adult carriers of paratyphoid infections are often submitted for necropsy as reactors to serological tests for pullorum disease or *S. typhi-murium* infection. Emaciation, necrotic ulcers in the intestines, enlarged liver, spleen or kidneys, nodules on the heart, and distorted ovules may occasionally be noted. Pathological changes in ovarian tissues as a result of paratyphoid infection are not as distinctive or common as observed in the case of chronic carriers of pullorum disease.

Chronically infected adults frequently exhibit no lesions. This is particularly true of intestinal carriers.

DIAGNOSIS

Clinical observations and necropsy findings may be suggestive of paratyphoid infection when a supportive history is available, and may permit one to reach a tentative diagnosis as a basis for early treatment or control recommendations. However, the final diagnosis of paratyphoid infections is dependent on the isolation and identification of the causative organisms. Procedures for this purpose require approximately 48 to 72 hours. The practicing veterinarian must usually rely on the state animal diagnostic laboratory for this service.

Biochemically and antigenically the members of the *Salmonella* genus are closely related not only to each other, but also to many other groups of the family *Enterobacteriaceae*, such as the Arizona and *Proteus* spp. Accurate identification of Salmonella and their differentiation from other closely related organisms often require detailed laboratory study. Specialized serological procedures necessary for the final identification of Salmonella types have been discussed under the section on Serology.

The bacteriologist or veterinarian engaged in the isolation of Salmonella cultures from poultry must be thoroughly familiar with the application of standard procedures for the culture and identification of members of the family *Enterobacteriaceae*. The manuals of Kauffmann (1950) and Edwards and Ewing (1962) on this subject are excellent laboratory references.

Serological tests have been applied only on a limited scale for the diagnosis of paratyphoid infections of poultry. This subject will be discussed in more detail in the section on Prevention and Control. Antigens used to test for paratyphoid infections may react positively to the serum of birds infected with pullorum disease, fowl typhoid, the Arizona, and other organisms. Bac-teriological examination must often be utilized to determine the presence of paratyphoid infections in reacting birds, especially when the reactions observed are of a suspicious nature. Thus, serological testing for paratyphoid should be regarded as a supplemental rather than a definitive diagnostic procedure.

In acute cases of paratyphoid infection in young birds, cultures should be prepared directly from the liver, spleen, heart blood, lungs, duodenum, and ceca. Additional organs or other portions of the intestinal tract may also be cultured if indicated. Mallmann *et al.* (1942), Poscll (1942), Hinshaw and McNeil (1943a), Gibbons and Moore (1946), Gauger and Greaves (1946c, 1947), and Chase (1947) have emphasized the importance of bacteriological examination of intestinal contents in attempting to determine the presence of paratyphoid infections in chicks and poults.

The culture of cloacal swabs taken from living birds has been studied as a diagnostic procedure for paratyphoid infection; however, this method is unreliable since fecal excretion of the organisms may be intermittent and it is impractical for use on a large scale (Wilson, 1948). Beattie (1960) indicated that fecal tests are not sufficiently reliable and, therefore, have limited application. These procedures may be employed, however, as a general measure in the detection of supply flocks that may contain Salmonella carriers. The bacteriological examination of yolk material from embryos dying between days 19 and 21 proved a practical method of detecting carrier flocks in Great Britain. Ellemann (1960) cultured 2,835 cloacal swabs from both chicks and adult hens in Sweden. Nine of the samples examined were found to contain 4 types of Salmonella organisms, and it was suggested that these were introduced into poultry flocks through contaminated imported feeds. Bierer and Vickers (1960b) examined cloacal swabs from nitrofuran-medicated, experimentally infected poults at 8 weeks of age. Swabs positive for *S. ty-*

phi-murium ranged from 0–33 per cent in the medicated birds and from 50–60 per cent in the nonmedicated control groups.

Cultures taken directly from fresh organs of diseased birds are made on beef-infusion agar slants or plates, which are incubated for 24 hours at 37° C. Intestinal cultures are subjected to selective enrichment in liquid broths after which they are streaked on selective agar plates. This technique is also useful in the bacteriological examination of specimens that are in a state of decomposition.

There are a large number of liquid enrichment broths and selective agars that have been recommended for the isolation of Salmonella cultures from fecal specimens. These have been reviewed by Edwards and Ewing (1962). Several media have been established, through practice, as most universally useful in the diagnosis of paratyphoid infections of poultry. For initial enrichment of fecal cultures most laboratories employ either tetrathionate broth with 1 to 100,000 brilliant green and 5 per cent bile, or selenite broth. Some laboratories use both of these media, which are available commercially in dehydrated form, in the examination of each fecal specimen. About 1 gram of fecal material is used to inoculate each 10 to 15 cc. of selective broth. Moran (1959b) reviewed procedures for the isolation, identification, and differentiation of Salmonella and Arizona strains. She strongly recommended the use of Kauffmann's tetrathionate enrichment medium, containing bile and brilliant green, and Kauffmann's brilliant-green agar for the isolation of Salmonella and Arizona cultures from intestinal contents. Stokes and Osborne (1955) and Osborne and Stokes (1955) developed a modified selenite brilliant-green medium for the isolation of Salmonella. This medium, through the addition of 0.05 per cent sodium sulfapyridine, was found to be sufficiently selective and sensitive to permit isolation of Salmonella, even when only one viable cell was present in 100 grams of commercial, naturally contaminated dried egg. Galton et al. (1952) reported that the addition of 0.125 mg. of sodium sulfathiazole to each 100 cc. of tetrathionate broth suppressed the multiplication of Proteus organisms. Jeffries (1959) found that tetrathionate containing 40 micrograms of novobiocin per milliliter of medium has proved better than plain tetrathionate as an enrichment medium for the isolation of Salmonella. The novobiocin was found to be very inhibitory for Proteus organisms. Galton (1961) reported the addition of 6 milliliters of a 10 per cent solution of Tergitol No. 7 to each 100 milliliters of tetrathionate brilliant-green broth for the isolation of Salmonella from animal feed products.

Enrichment broths are incubated for 18 to 24 hours at 37° C. before streaking on selective solid media. The most widely employed selective plating agars include SS agar, MacConkey agar, brilliant-green agar (Kauffmann, 1950), and desoxycholate citrate-lactose-sucrose agar. There is some variation in preferences for these plating media among various diagnostic laboratories. Edwards et al. (1948c) stated that the most satisfactory method for the examination of intestinal material from fowl for paratyphoid organisms is the use of tetrathionate brilliant-green broth plated after 24 hours' incubation on the brilliant-green agar of Kauffmann (1950).

Bloom et al. (1958), in culture studies of sewage, found a selenite brilliant-green enrichment medium to be superior to tetrathionate broth in the isolation of Salmonella. Dixon (1961) found that plating of selenite F enrichment cultures on a brilliant green MacConkey agar after 6 hours incubation at 43° C. added significantly to the number of positive isolations of Salmonella. Yamamoto et al. (1961b) did not find the number of Salmonella in turkey feces to change appreciably when samples were held 21 to 48 hours at 4° C. Ringer's solution and Hajna's preservative were effective as suspending media to maintain the organisms. Selenite-cystine broth enrichment with subsequent plating on brilliant-green agar gave the most favorable results in the isolation of *S. typhi-murium*

from infected tissues and other material.

Methods for the bacteriological examination of reactors to serological tests for paratyphoid infections are identical to those used in the laboratory examination of reactors to the pullorum test. Jungherr et al. (1950) outlined procedures for the bacteriological examination of reactors to serological tests for pullorum disease. Yamamoto et al. (1962) outlined cultural procedures for the examination of turkeys reacting to serological tests for S. typhimurium. Standard procedures for the isolation of Salmonella from poultry vaccines of egg-embryo origin have also been described (Anon., 1954).

Because of the interest in Salmonella organisms occurring in poultry feedstuffs, recommended procedures for the isolation of Salmonella organisms from animal feeds and meat by-products have been developed and published (Anon., 1962). Hobbs (1963) discussed in detail techniques for the isolation of Salmonella organisms from eggs and egg products. Papadakis (1960) developed a dulcitol-sucrose-salicin-iron-urea agar for the differential diagnosis of Salmonella, Proteus, and Arizona cultures. Since 1951 the Research Committee of the North Central Regional Poultry Disease Conference has conducted a comparative study of various culture media and techniques for the recovery of Salmonella from adult birds submitted for bacteriological examination as reactors to blood tests. The results of this study were published in the 1952 and 1953 Proceedings of the Conference. At the 1954 Conference the results of various surveys were summarized, and this information was used as a basis for the standard procedures for the examination of reactors to Salmonella serological tests which are published in the National Poultry and Turkey Improvement Plans and Auxiliary Provisions (Anon., 1963b).

The tissues most frequently selected for culture from serological reactors are the heart, liver, lungs, gallbladder, ovary, testes, oviduct, pancreas, and spleen. A composite sample of the above organs may be triturated in a sterile mortar, ground in a blender, or the organs may be processed individually. Nutrient broth is usually used as a diluent, and the suspensions are inoculated in 10 cc. aliquots per 100 cc. of selective broths such as tetrathionate brilliant-green, selenite, and a noninhibitory nutrient broth. Selective plating media are streaked from the broths after 18–24 hours at 37° C. If suspicious colonies are not observed on the plates after 24 hours' incubation, the enrichment broths may be restreaked on solid media. Intestinal cultures from reactors are prepared as described previously for young birds.

All selective plating media are examined after 24 hours' incubation at 37° C. for colonies typical of Salmonella. Suspected colonies are picked by touching the tip of a platinum needle to the center of the colony and transferred by stab and streak to the triple sugar iron (TSI) agar slants. The inoculated tubes are incubated for 24 hours at 37° C. Slants which have a typical acid butt (yellow) with or without gas and an alkaline slant (red) are selected for further study as possible Salmonella cultures. Hydrogen sulfide production is indicated by blackening of the agar due to iron sulfide precipitation. Sieburth (1957b) reported the development of a lactose urea agar in combination with a mannitol semisolid agar for the differentiation of Salmonella from other closely related enteric organisms. Ewing et al. (1960) described the deamination and carboxylase reactions of Salmonella and Arizona strains and pointed out their value in taxonomy of the groups.

In order to eliminate Proteus spp., it is advantageous to test the suspected Salmonella cultures for urease production. The urea agar of Christensen (1916), which permits a reading in 6–8 hours, or the rapid urease test of Stuart et al. (1945) may be used.

Those cultures that are negative to the urease test should be transferred to the following media for final identification: dextrose, lactose, sucrose, mannitol, maltose, dulcitol, malonate, and salicin; peptone medium for indol production; semi-

solid medium for motility; and gelatin. A
Gram stain of each culture should also be
prepared. Checking of each culture with a
polyvalent Salmonella typing serum is
helpful in identification.

Typical reactions of paratyphoids, Ari-
zona, and Citrobacter on diagnostic media
are listed in Table 9.3.

Garside et al. (1960) used phage-typing
of S. typhi-murium in distinguishing a sin-
gle strain of this organism in experimental
studies of antibiotic resistance. Anderson
and Wilson (1961) have described a bac-
teriophage-typing scheme for S. typhi-mu-
rium strains of animal origin. They sug-
gested that the more extensive veterinary
use of this procedure will aid in tracing the
distribution of particular types of S. typhi-
murium infection in animals. Marthedal
(1962) used a biochemical and serological
scheme for classifying S. typhi-murium
strains of avian origin in Denmark.

TREATMENT

Medicinal therapeutic measures may be
employed to reduce mortality in acute
outbreaks of paratyphoid infections and
to aid in preventing the development and
spread of the disease. All such measures
have the disadvantage of being incapable
of eliminating the infection from treated
birds. The demonstration by Yurchenco
et al. (1953) that certain of the furan ring
type of chemicals (nitrofurans) have

marked activity against Gram-negative
bacteria opened a new field in the ther-
apy of Salmonella infections of poultry.
Wolfgang (1958) reviewed recent progress
in nitrofuran research.

The use of chemical therapeutic meas-
ures for paratyphoid infections in domes-
tic poultry flocks should be restricted to
flocks intended for market use. Young
birds that have undergone an acute out-
break of paratyphoid infection, even when
drug therapy is used, are not a safe source
of future breeding stock. Birds that have
received treatment may remain carriers of
the organisms as therapeutic measures are
not capable of completely eliminating the
infection. It should always be remembered
that while advances have been made in the
prevention of paratyphoid and reduction
of losses through treatment, therapeutic
measures are of little value in any long-
range program to eliminate paratyphoid
infections from poultry flocks.

Individual or flock therapy may be in-
dicated in acute outbreaks of paratyphoid
infections among birds maintained in zo-
ological parks, for treating household pets
such as parakeets or canaries (Burkhart et
al., 1962), and for flocks of wild birds main-
tained on refuges (Lucas, 1956 and Jones,
1959).

The sulfonamide drugs have been dem-
onstrated to have some effect in reducing
the mortality from paratyphoid infections.

Sulfamethazine and sulfamerazine have been most widely used and are usually administered as feed additives. Feeding of the sulfonamides at the therapeutic level should be intermittent to prevent the development of toxicity from the treatment. Turkey poults are particularly susceptible to the toxic effects of the drugs. Soluble forms of some of the sulfonamide drugs are available for addition to the drinking water. This method of administration is advantageous when the birds do not consume feed in quantity. Sulfonamide-resistant bacterial forms may develop from continued treatment.

Clark (1916) reported that sulfamerazine in the mash at a level of 0.3 per cent or higher was effective as a prophylactic measure against paratyphoid infections of chicks and poults. Peterson (1947) encountered a serious outbreak of S. typhi-murium infection in which sulfamerazine at a 0.5 per cent concentration in the mash was ineffective. Eveleth et al. (1947) reported that 0.4 per cent sodium sulfamerazine in the drinking water or 0.5 per cent sulfamerazine in the mash was found useful in reducing death losses from paratyphoid infections in poults and chicks. Pomeroy et al. (1948) reported that sulfamethazine, sulfadiazine, and sulfamerazine reduced death losses from S. typhi-murium infection in chicks 50 per cent; however, the drugs proved to be only one-half as effective when fed to poults. Price et al. (1962) used soluble sulfamethazine in the drinking water at the rate of 1 ounce per gallon of water for 2 days in the treatment of salmonellosis of ducklings.

The antibiotics have not been extensively used in the treatment of paratyphoid infections of poultry. In general, they have proved less effective than other medicinal treatments that are available. Lukas and Bradford (1951) reported that Terramycin and chlortetracycline (Aureomycin) were the drugs of choice in controlling paratyphoid outbreaks in poults. The effective concentrations were 100 p.p.m. of soluble Terramycin in the water and 250 grams of Terramycin or chlortetracycline per ton of

feed. The duration of treatment was determined by the flock response. Other flocks that received sulfonamide therapy had a higher percentage of losses and stunted birds than did the antibiotic-treated group. Garside et al. (1960) found that chlortetracycline gave a measure of protection against artificial infection with S. typhi-murium in chicks, the mortality rate in antibiotic-fed chicks being approximately one-half that in chicks not receiving the antibiotic.

Thiocymetin (Shaffer et al., 1954) and synnematin B (Olson and Jennings, 1954), two newer antibiotics, have shown encouraging results in experimental applications for the treatment of avian salmonellosis.

Ravioli and Orfei (1953) found Chloromycetin and Terramycin to change the fermentative properties of Salmonella isolated from treated birds. McCarty (1953) reported neomycin to be beneficial in the treatment of S. derby infection in geese, and Schoop and Moser (1954) reported that streptomycin was used with some success in the therapy of pigeons infected with S. typhi-murium.

Mitrovic et al. (1961) tested the sensitivity of 20 Salmonella types in vitro to a new chemotherapeutic agent, 3, 5-dinitrobenzamide. The organisms were sensitive to the drug at levels of 1.0, 5.0, and 10.0 mg. per test disc. In vivo studies revealed that the compound reduced mortality in S. typhi-murium-infected poults when fed either 3 days before, simultaneously with, or 1 day after infection.

Furazolidone [N-(5-nitro-2-furfurylidene)-3-amino-2-oxazolidone], one of the nitrofuran derivatives of furfural, has been found to be effective in reducing mortality in acute outbreaks of several types of paratyphoid infections. Subtherapeutic levels of the drug are recommended to decrease the development and spread of paratyphoid infections. Furazolidone is marketed under the trade name, nf-180.

In recommended concentrations, furazolidone has a low toxicity for host tissues and acts by interrupting the enzymatic metabolic processes of the microbial cell.

drug was found to be effective in lowering death losses from the infection and also in increasing the body weights of birds being treated.

Belding and Mayer (1958) reported that furazolidone added to the mash of poults at the level of 0.011 per cent for 2 weeks followed by a 0.0055 per cent level for 3 weeks reduced the mortality due to *S. san diego* infection by 50 per cent. Treatment was started at the time the poults were experimentally infected. Aureomycin and sulfamethazine were found to have no appreciable effect in reducing mortality due to the infection. Treatment with either Aureomycin and sulfamethazine or furazolidone reduced the number of infected carriers.

Bierer and Vickers (1960a) studied the effect of 4 nitrofurans on *S. typhi-murium* infection induced experimentally in poults. Results were inconclusive, and none of the nitrofurans used was completely successful in eliminating carriers of *S. typhi-murium* from the infected groups. Bierer and Vickers (1960b) found that furazolidone in the feed or soluble nitrofurans in the drinking water drastically reduced mortality from experimentally induced *S. typhi-murium* and *S. heidelberg* infection in poults. The soluble nitrofurans used were NF-248 and solubilized furaltadone at the level of 0.0066 and 0.0264 per cent, respectively, in the drinking water. These drugs did not depress water consumption. Solubilized furaltadone would have been the nitrofuran of choice if it was not feasible or desirable to medicate through the feed. Bierer *et al.* (1961c), in further studies of water-soluble furaltadone medication, found that the drug administered at the rate of 0.25 gm/gal of water resulted in a marked reduction in mortality from *S. typhi-murium* infection in poults. Using furaltadone prophylactically in the drinking water at the levels of 0.25, 0.5, and 1 gm/gal, Bierer and Barnett (1962b) found the drug to reduce mortality from *S. typhi-murium* infection in turkey poults from 70–80 per cent to 20–30 per cent. Bierer (1963) reported that both 0.011 per cent and 0.0165 per cent nihydrazone (Nidra-

fur) reduced mortality due to *S. typhi-murium* infection in turkey poults. However, this drug seems to retard growth at effective therapeutic levels in turkeys.

Lucas (1956) reported that furazolidone at the level of 0.011 per cent in the feed was used successfully to control an outbreak of *S. typhi-murium* and *S. anatum* infections in wild mallard ducks. Tablets of the drug were also found to be effective in individual treatment at a dosage of 50 mg. daily. Agglutination tests using *S. anatum* and *S. typhi-murium* antigens revealed the presence of reactors after treatment. Truscott (1956) found that a level of 0.011 per cent furazolidone in the feed did not alleviate an outbreak of salmonellosis among ducklings. However, when the concentration was increased to 0.0165 per cent and strict sanitation measures instituted in the brooding pens, the infection was brought under control. Price *et al.* (1962) indicated that treatment of paratyphoid-infected ducklings was usually limited to rigid culling. Sulfamethazine in the drinking water was recommended as medication in more serious outbreaks.

Jones (1959) recommended furazolidone as the drug of choice in the treatment of Salmonella and Arizona infections of game birds. Francis *et al.* (1960) reported that pheasants and quails may effectively be treated for salmonellosis with 0.011–0.022 per cent furazolidone for 7–10 days followed by 0.0055 per cent for another 7–10 days.

Keymer (1959) recommended a compound consisting of nitrofurazone and furazolidone added to the drinking water in the treatment of salmonellosis of canaries and other passerine birds. Treated birds may remain carriers of the organisms. Burkhart *et al.* (1962) reported treatment of parakeets and canaries with several watersoluble nitrofurans following experimental paratyphoid infections. Furaltadone (NF-260) and a second nitrofuran (NF-248) in a 6 per cent propylene carbonate solution, administered in the drinking water, controlled *S. typhi-murium* infection in parakeets when used for 2 weeks at the level of

preventing cell multiplication (Paul, 1956). The drug has a low solubility which permits the extended maintenance of a rather high concentration in the intestinal tract of treated birds. Smith (1955) demonstrated, however, that furazolidone is usually totally absorbed near the middle of the avian intestinal tract. The drug is generally administered at a concentration of 0 0055 per cent (50 grams per ton) fed in the mash on a continuous basis as a preventive of paratyphoid infections in birds over 2 weeks of age or at the level of 0.011 per cent (100 grams per ton) as a preventive in birds during the first 2 weeks after hatching. A dosage schedule of 0.011 per cent to 0.022 per cent (200 grams per ton) in the mash fed for 2 weeks is recommended for treatment of acute outbreaks of paratyphoid infections The drug is usually added at the required level by the feed manufacturer.

Paratyphoid organisms are apparently more resistant than S pullorum and S. gallinarum to the inhibitory action of furazolidone both in laboratory tests and in field therapy trials. Smith (1955) during in vitro sensitivity studies found that the 9 strains of S. typhi-murium included in his tests were 2 to 4 times as resistant to furazolidone as was S. pullorum. Harwood (1956) indicated that furazolidone only rarely eliminated paratyphoids from infected birds although clinical response in reducing mortality from the disease was excellent.

Smith (1955) reported that furazolidone fed at a level of 0.04 per cent in the mash continually for 10 days was very effective in reducing the mortality associated with experimental S. typhi-murium infection in poults and chicks. It was found that a high proportion of treated birds become carriers of S. typhi-murium even when treatment was started 3 days before infection. The organisms were more frequently recovered from the feces than from the organs of experimentally infected birds Repeating the treatment or increasing the concentration of furazolidone was not found to decrease the carrier rate.

Wilson (1955) conducted experiments to test the efficacy of furazolidone in treating S. typhi-murium and S. thompson infections in chicks. Both 0.02 per cent and 0.04 per cent levels of the drug were used in these experiments. Results were inconclusive as the disease did not develop to any degree in control groups that received no treatment. Harwood (1956) suggested that a combination treatment of furazolidone and sulfonamide may prove useful in reducing losses in extremely severe paratyphoid epizootics of poultry.

Sieburth (1957a) studied the effect of 0.011 per cent furazolidone on the mortality rate of chicks experimentally infected with S. typhi-murium at 1 day of age. Uninfected controls and furazolidone-treated groups both experienced 7 per cent mortality while the infected groups that received no treatment experienced a mortality of 27 per cent. However, 100 per cent of the intestinal cultures and a majority of the organ pools from the surviving chicks contained detectable numbers of S. typhi-murium. The drug also had an inhibitory effect on the development of S. typhi-murium agglutinins detectable by a conventional agglutination test. Agglutinins were demonstrable, however, through the use of an indirect hemagglutination test.

Beattie (1960) reported that he used furazolidone with excellent results in the treatment of experimental S. thompson infection in chicks. Lannek et al. (1962) reported studies of the nitrofurazone compound, Tiafur, in the treatment of experimental and spontaneous Salmonella infections in chicks. Mortality was considerably reduced and clinical symptoms were markedly suppressed by a level of 0.1 per cent of Tiafur in the feed. A long-time treatment with small doses (0.01 and 0.04 per cent) gave more chicks the chance to survive without eliminating infection, and consequently left more carriers. Bierer and Barnett (1962a) studied the use of the nitrofuran feed additive, Nihydrazone (Nidrafur), at the 0.011 and 0.022 per cent levels, in the therapy of incubator-induced S. typhi-murium infection in chicks. The

drug was found to be effective in lowering death losses from the infection and also in increasing the body weights of birds being treated.

Belding and Mayer (1958) reported that furazolidone added to the mash of poults at the level of 0.011 per cent for 2 weeks followed by a 0.0055 per cent level for 3 weeks reduced the mortality due to *S. san-diego* infection by 50 per cent. Treatment was started at the time the poults were experimentally infected. Aureomycin and sulfamethazine were found to have no appreciable effect in reducing mortality from the infection. Treatment with either Aureomycin and sulfamethazine or furazolidone reduced the number of infected carriers.

Bierer and Vickers (1960a) studied the effect of 4 nitrofurans on *S. typhi-murium* infection induced experimentally in poults. Results were inconclusive, and none of the nitrofurans used was completely successful in eliminating carriers of *S. typhi-murium* from the infected groups. Bierer and Vickers (1960b) found that furazolidone in the feed or soluble nitrofurans in the drinking water drastically reduced mortality from experimentally induced *S. typhi-murium* and *S. heidelberg* infection in poults. The soluble nitrofurans used were NF-248 and solubilized furaltadone at the level of 0.0066 and 0.0264 per cent, respectively, in the drinking water. These drugs did not depress water consumption. Solubilized furaltadone would have been the nitrofuran of choice if it was not feasible or desirable to medicate through the feed. Bierer et al. (1961c), in further studies of water-soluble furaltadone medication, found that the drug administered at the rate of 0.25 gm/gal of water resulted in a marked reduction in mortality from *S. typhi-murium* infection in poults. Using furaltadone prophylactically in the drinking water at the levels of 0.25, 0.5, and 1 gm/gal, Bierer and Barnett (1962b) found the drug to reduce mortality from *S. typhi-murium* infection in turkey poults from 70–80 per cent to 20–30 per cent. Bierer (1963) reported that both 0.011 per cent and 0.0165 per cent nihydrazone (Nidra-

fur) reduced mortality due to *S. typhi-murium* infection in turkey poults. However, this drug seems to retard growth at effective therapeutic levels in turkeys.

Lucas (1956) reported that furazolidone at the level of 0.011 per cent in the feed was used successfully to control an outbreak of *S. typhi-murium* and *S. anatum* infections in wild mallard ducks. Tablets of the drug were also found to be effective in individual treatment at a dosage of 50 mg. daily. Agglutination tests using *S. anatum* and *S. typhi-murium* antigens revealed the presence of reactors after treatment. Truscott (1956) found that a level of 0.011 per cent furazolidone in the feed did not alleviate an outbreak of salmonellosis among ducklings. However, when the concentration was increased to 0.0165 per cent and strict sanitation measures instituted in the brooding pens, the infection was brought under control. Price et al. (1962) indicated that treatment of paratyphoid-infected ducklings was usually limited to rigid culling. Sulfamethazine in the drinking water was recommended as medication in more serious outbreaks.

Jones (1959) recommended furazolidone as the drug of choice in the treatment of Salmonella and Arizona infections of game birds. Francis et al. (1960) reported that pheasants and quails may effectively be treated for salmonellosis with 0.011–0.022 per cent furazolidone for 7–10 days followed by 0.0055 per cent for another 7–10 days.

Keymer (1959) recommended a compound consisting of nitrofurazone and furazolidone added to the drinking water in the treatment of salmonellosis of canaries and other passerine birds. Treated birds may remain carriers of the organisms. Burkhart et al. (1962) reported treatment of parakeets and canaries with several water-soluble nitrofurans following experimental paratyphoid infections. Furaltadone (NF-260) and a second nitrofuran (NF-248) in a 6 per cent propylene carbonate solution, administered in the drinking water, controlled *S. typhi-murium* infection in parakeets when used for 2 weeks at the level of

300 mg. total nitrofuran per liter of water. This combination at 150 and 200 mg. levels gave 100 per cent protection against *S. typhi-murium* infection in canaries. It was emphasized that increased water consumption during paratyphoid infections makes the use of water-soluble nitrofurans preferable. Also pet birds like parakeets and canaries consume seeds which makes it impossible to administer the drugs in the feed.

Bacterins, serums, or similar biologicals are not effective in either the prevention or treatment of paratyphoid infections of poultry.

PREVENTION AND CONTROL

Adult intestinal carriers serve as the chief source of paratyphoid infections in most species of poultry. Fecal contamination of hatching eggs by the chronic carrier or from an infected environment is the means by which the infections are generally introduced into the incubator and subsequently into the brooder. Because of the wide natural distribution of Salmonella organisms, the numerous antigenic types, and the lack of adequate methods to detect carriers among adult flocks, *hatchery and flock sanitation is the most important factor in the prevention and control of paratyphoid infections of poultry.*

Flocks that experience acute outbreaks of paratyphoid with high losses at a young age, or those that are known to carry the infection at any age, should not be used as a source of eggs for hatching purposes. Early disposal of such flocks is usually the most desirable program to follow. Agglutination tests have been employed to detect infected flocks; however, procedures for this purpose have not been developed to the degree of accuracy of serological tests for the detection of pullorum disease and fowl typhoid. For prevention of the infections, replacement stock and hatching eggs should be obtained from a source that is known to be paratyphoid free. The birds should be maintained at all times in an environment where exposure to the organisms is kept

at a minimum. Goetz (1962) discussed the California program used for the control of *S. typhi-murium* and Arizona infections in turkeys. The program is based on the following principles: (1) Stocking the breeding flock from a known clean source; (2) bacteriological sampling of all poult mortality up to 21 days of age; (3) tube agglutination testing of all potential breeding stock with *S. pullorum*, *S. typhi-murium*, and Arizona antigens; and (4) routine bacteriological examination of samples of 10-day-dead embryos from the hatchery.

Paratyphoid infections, when encountered in valuable breeding stock, constitute a particular problem. Special measures are necessary in such cases, and eradication efforts often extend over a period of several years involving considerable financial loss. The most practical way to control the disease among birds in the pet or bird store is by means of depopulation and thorough cleaning and disinfection of the premises. A critical examination should be made of the source of supply for replacements in order to prevent recurrent infection.

An effective program for the prevention and control of paratyphoid infections of poultry should give consideration to the following measures:

1. Hatchery and egg sanitation. The use of only clean eggs for hatching purposes will lessen the chances of introducing the infection into the incubator through fecal contamination. Adequate numbers of nests and clean laying houses should be provided. Eggs should be collected at frequent intervals, fumigated, and stored in a cool place for as short a period as possible before setting. Cleaned and disinfected containers should be used in collecting the eggs, and the person making the collections should be certain that he does not serve as a source of contamination from organisms that may be present on his clothing or hands. Dirty eggs should not be used for hatching purposes, and should be collected in a separate container from hatching eggs.

Racks or crates used for storing eggs

should be new or properly cleaned and disinfected. Contact of the eggs should be kept at a minimum during storage since one egg or may serve as a source of contamination for many others. Maclaury and Moran (1959) stressed the fact that if warm, freshly laid eggs do not come in contact with contaminated soil or fecal material while they are cooling, the chances of their being infected with Salmonella organisms are greatly decreased. If it is necessary to transport eggs before setting, new crates are most desirable for this purpose. Dirty crates should never be used. Pomeroy (1958) has pointed out that contaminated eggshells may serve as an important means of introducing Salmonella and Arizona organisms into a hatchery. Attention to sanitation on the farm at the supply flock level to obtain Salmonella-free hatching eggs is an essential part of a paratyphoid control program.

Dipping or washing dirty eggs before setting is not recommended as this practice may contribute to the penetration of the eggshell by Salmonella organisms that are present on the surface. Quaternary ammonium compounds, formalin, sodium hydroxide, and sodium orthophenylphenate have been studied for this purpose (Wilson, 1948); however, most investigators are not convinced that this is a practical or effective procedure for the prevention of salmonellosis. Frank and Wright (1956) reported that 0.5 per cent sodium hydroxide was effective within 5 minutes in disinfecting pieces of eggshell infected with S. typhi-murium. However, dipping whole eggs in sodium hydroxide at concentrations up to 2 per cent for 5 minutes failed to prevent penetration of the eggshell by the organism both at incubator and room temperature. It was felt that penetration of the shells may have occurred before the disinfectant had a chance to act or that the organism was protected by some physical property related to the pores of the shell.

Mundt and Tugwell (1958) and Beattie (1960) have suggested dipping eggs in germicides as a reliable method of control. Bierer et al. (1961a) found that none of 24 chemical egg-washing compounds was ef-fective in killing S. typhi-murium when used at 2.5–4 times manufacturer's recommendations. Quaternary ammonium compounds were found to be entirely unsatisfactory. One per cent zinc sulfate was found to be superior to the other chemicals used from the standpoint of causticity, toxicity, odor, and staining. Bierer et al. (1961b) used 8 commercial compounds advertised as detergents or detergent-sanitizers in egg-washing experiments. The compounds were from 52 to 92 per cent efficient in removing or destroying artificially induced S. typhi-murium eggshell contamination. Bierer and Barnett (1961) demonstrated that egg-wash germicides should be tested at 38° C. or lower to avoid the germicidal effect of the water itself in experimental studies.

Early fumigation of the eggs with formaldehyde gas has been found to be very effective in the prevention of egg-borne paratyphoid infections. Wilson (1949) stated that fumigation of eggs with formaldehyde gas is probably the most important factor in paratyphoid prevention. Recommendations on the application of formaldehyde gas as an incubator fumigant for the prevention of pullorum disease are discussed in the chapters Principles of Disease Prevention and Pullorum Disease.

Egg fumigation for the prevention of pullorum disease is generally recommended for application toward the end of the incubation period. Since paratyphoid infections, unlike pullorum disease, are usually transmitted through penetration of the eggshell by organisms on its surface, early fumigation is required. Marcellus et al. (1939) have demonstrated that the embryos are most susceptible to injury from formaldehyde gas during the 24th and 96th hours. Fumigation during this period is to be avoided.

Lancaster (1962) reviewed information relating to formaldehyde fumigation of eggs with high levels of the gas. It was pointed out that earlier studies on the period of maximum susceptibility of embryos are not necessarily applicable when higher levels of the fumigant are used. With these

larger amounts the period of embryonic susceptibility appeared to be prolonged from the second to the sixth or even eighth day of incubation. Since Harry and Binstead (1961) were able to demonstrate that hatchability may be adversely affected when embryos are exposed to high levels of formaldehyde gas between the third and ninth day of incubation, preincubation fumigation as a standard procedure was highly recommended. The degree to which hatchability was affected was influenced by the particular flock involved and the preincubational storage period.

Fumigation of hatching eggs as soon as possible after collection is highly recommended. A room or cabinet sized proportionally to the number of eggs should be provided. Fans can be used to circulate and exhaust the gas from enclosed areas. Eggs for fumigation should be placed on racks which will permit good air circulation. Formaldehyde gas is provided by mixing 0.6 gram of potassium permanganate with 1.2 milliliters of formalin (37.5 per cent) for each cubic foot of space in the cabinet or room. The chemicals should be mixed in an earthenware or enamelware container having a capacity of at least 10 times the volume of the total ingredients. The gas should be circulated within the enclosure for 20 minutes, then expelled. Humidity for this type of fumigation is not critical, but the temperature should be around 70° F. Extra humidity may be provided in dry weather.

When preincubation fumigation is impossible, eggs should be fumigated as soon as possible (preferably within 12 hours) after setting. After allowing temperature and humidity to regain normal operating levels, formaldehyde gas should be released into the incubator. For each cubic foot in the incubator, 0.4 gram of potassium permanganate and 0.8 milliliter of formalin (37.5 per cent) are used. Doors and vents should be closed with circulating fan operating for a 20-minute period of fumigation with normal operating temperature and humidity. After fumigation, vents should be opened to the normal operating

positions to release the gas (Anon., 1963b). An illustrated bulletin in which the importance of preincubation fumigation of turkey hatching eggs is discussed has been published by the California Department of Agriculture (Stover, 1960).

Buxton and Gordon (1947), Wilson (1948, 1949, 1951), Clarenburg and Roepke (1952), Lancaster and Crabb (1953a, b), Lancaster et al. (1954), Harry (1954), Clarenburg and Romijn (1954), and Frank and Wright (1955), have studied the use of formaldehyde gas in the fumigation of eggs and incubators contaminated with paratyphoid organisms. Buxton and Gordon (1947) and Wilson (1949) have recommended that fumigation for the destruction of paratyphoid organisms on the shell surface should be done before incubation. Penetration of the shell was found to proceed far more rapidly in the warm, humid atmosphere of the incubator, and usually to occur during the first week of incubation.

Wilson (1951) recommended the fumigation of eggs for a period of 30 minutes with formaldehyde gas produced by the addition of 150 ml. of formalin to 100 grams of potassium permanganate per 100 cubic feet of incubator space. This concentration of the gas was invariably lethal for S. typhi-murium on eggshells and on down, and normally had no adverse effect on hatchability if certain precautions as to the time of application were taken. Humidity was not a factor as this treatment was found to be effective even under ordinary atmospheric conditions. The high concentration of the gas was recommended particularly following an actual outbreak of paratyphoid infection.

Frank and Wright (1955) studied the susceptibility of 19 Salmonella serotypes to formaldehyde fumigation. Test organisms were placed on pieces of eggshell and string. Fumigation with 150 milliliters of formalin and 75 grams of potassium permanganate per 100 cubic feet of incubator space killed all organisms in 20 minutes, while a number survived 10 minutes fumigation. When 100 milliliters of formalin

and 50 grams of potassium permanganate per 100 cubic feet were used, 30 minutes were required to kill all organisms. *S. pullorum* was found to be more susceptible than the paratyphoids to the lethal effects of the formaldehyde gas.

For routine fumigation of eggs to destroy paratyphoid organisms Wilson (1951) recommended the use of 75 ml. of formalin and 50 grams of potassium permanganate per 100 cubic feet of incubator space with a dry bulb reading of 100° F. and wet bulb reading of 90° F. A suitable time for fumigation was found to be 6–8 hours after the eggs were set. A later fumigation toward the end of the incubation period is of further value in the prevention of incubator spread of the disease. Harry (1954) found that the removal of residual formaldehyde remaining after fumigation could be accomplished by adding 33 per cent ammonia solution to the incubator in a volume equal to one-half that of the formalin used. This limited the escape of irritant concentrations of formaldehyde from the incubators.

When an air-borne infection of Salmonella organisms has become established in a hatchery it may be necessary to fumigate the entire hatchery with high levels of formaldehyde gas to destroy the organisms. Close attention should also be given to contaminated egg sources which are usually responsible for introduction of the infection into the hatchery. Blood testing and the culture of eggs from supply flocks are often useful adjuncts in locating the source of the infection.

Price *et al.* (1962) recommended that duck eggs be fumigated on the second day of incubation for a period of 15 minutes and prescribed the use of 1 ounce of formalin and one-half ounce of potassium permanganate to every 80 cubic feet of incubator space. Rasmussen (1962) also discussed hygienic measures to control the spread of duck salmonellosis.

After each hatch, incubators should be thoroughly cleaned of the debris of the hatch, washed with detergent and hot water, disinfected, and fumigated with a

bigh level of formaldehyde gas. At least 0.6 gram of potassium permanganate and 1.2 milliliters of formalin (37.5 per cent) per cubic foot of incubator space should be used with an exposure of 1 hour. Higher levels of the gas may be used if desired. General disinfection procedures for incubators and hatching rooms are discussed in Chapter 5.

Restrictions should be placed on hatchery personnel to insure that they do not introduce the infections into the hatchery from older fowl or from other animals with which they come in contact in their daily operations. It should be determined that no human carriers exist among the personnel. Visitors to the hatching area should be kept to a minimum. Boxes used to ship birds should be new, and trucks employed for transporting operations should be kept clean and be frequently disinfected. There should be a constant campaign to eliminate rats, mice, and flies in the vicinity of the hatchery.

2. Sanitation during the brooding period. For prevention of paratyphoid infections during brooding it is important that the young birds be constantly isolated from sources of the infection. Personnel that are in contact with older birds and with other animals should take precautions not to introduce the infection through droppings that may adhere to the shoes, clothing, or hands. It is a good practice under these conditions to wear overshoes that can be disinfected, and also coveralls that can be frequently changed. Bierer (1960) emphasized the importance of starting young turkey poults on cleaned and disinfected premises and possibly administering preventive medication in the initial feed and water in preventing paratyphoid infections.

All types of animals should be restricted from the brooding area. Feed and water containers should be situated where they cannot be contaminated by droppings and should be frequently cleaned and disinfected. Live steam is very effective for this purpose. A detailed sanitation program for the poultry industry has been outlined

(Anon., 1947) in which cresylic disinfectants are recommended. The standard dilution of cresylic disinfectant used is 4 fluid ounces to each gallon of water (about 3 per cent). Commercial lye, 2 per cent in water, is also a very effective disinfectant when used as a hot solution. Odorless disinfection is available through the use of sodium orthophenylphenate in an aqueous or detergent solution.

Young birds that die or are sick should be promptly submitted to the diagnostic laboratory for examination. It is the responsibility of the laboratory to conduct complete bacteriological examinations to detect any Salmonella that may be present. All Salmonella cultures isolated should be typed serologically and up-to-date and complete records maintained relative to the Salmonella types recovered from each flock within an area. This information is essential in guiding the use of specific antigens in serological tests for the disease in breeding flocks. Information derived from typing the organisms also aids in tracing the origin of disease outbreaks. Periodic summarizing of this information within each state would be most helpful to those engaged in paratyphoid control activities.

3. Flock sanitation. Rodents and various pests around the poultry yards serve as an important source of Salmonella organisms for semimature and adult flocks. Mice and rats may pass large numbers of the organisms in their excreta and are able to contaminate feed supplies and water, as well as litter and the poultry yards. It is hoped that a satisfactory sanitation code may be developed and adopted to insure that Salmonella organisms are not present in the feed which the flock consumes. This hazard must be removed before other control measures can be effectively applied. An active rodent eradication campaign is an essential part of the general Salmonella control program. Dogs, cats, sheep, cattle, horses, and swine should never have access to poultry operations.

Birds that have received therapy for paratyphoid infections should not be kept for breeding purposes. Neither should breeding flocks be treated for these infections and then maintained as a source of hatching eggs. Garside et al. (1960) found that a large number of carriers remained among groups of chicks receiving therapeutic levels of chlortetracycline. They emphasized that such a practice increases the problem of the control of salmonellosis in poultry. Goetz (1962) reported an incidence in which it was necessary to abandon turkey raising operations in one area because S. typhi-murium was indigenous in the wildlife of the area. The organism was isolated from gopher snakes, ground squirrels, and owls shot on the premises.

4. Serological testing. Procedures for the serological detection of adult carriers of paratyphoid infections have not been accepted or applied on the scale of those employed for the detection of pullorum disease and fowl typhoid. The tube agglutination test for S. typhi-murium has been most frequently used as a supplementary measure to other means of control or as a method for locating infected flocks. This procedure has been most widely applied in testing turkey breeding flocks.

Intestinal carriers may reveal no serological response to the agglutination test, and titers of birds that do react may fluctuate widely as reported by Pomeroy and Fenstermacher (1943), Buxton and Gordon (1947), and Lee (1957). Testing programs for paratyphoids are further complicated by the large number of antigenic types of the organism infecting poultry and the need for refinements in methods of producing antigens for the test.

Buxton (1958) noted that the agglutination test is of value in controlling salmonellosis of turkeys provided it is used in conjunction with hygienic measures to prevent reinfection. The agglutination test was found to give some idea of the rate of multiplication of the organism in the host and the carrier animal usually revealed a low titer. Bierer and Vickers (1960a) reported that in nitrofuran-medicated poults there was a definite suppression of agglutinin production to the extent that S. typhi-

murium experimentally-infected birds treated with nitrofurans did not react to any serological tests.

Specific antigens for the Salmonella type involved must be prepared in the laboratory. Laboratory personnel conducting the tests and interpreting the results must be thoroughly familiar with Salmonella serology and the variations that may arise during testing procedures. The history of each flock tested must be carefully considered. Representative reactors to the agglutination test should be submitted for complete bacteriological examination and laboratory confirmation of the presence of the infection.

The agglutination test has been applied in testing most species of fowl for paratyphoid. The use of the test has been sporadic in most areas, being applied as conditions warranted. In 1964 approximately 6 states in the United States were using the test on a large scale to detect *S. typhimurium* in turkey breeding flocks. At least 3 states (Minnesota, California, and Texas) have official rules and regulations including blood testing programs that have been adopted for the control of *S. typhi-murium* infection of turkeys. In a committee report (Anon., 1958a) it was suggested that if a designation or classification is needed for a flock under a voluntary *S. typhimurium* testing program, a classification such as "*S. typhi-murium* tested and no reactors found" should be considered. Pomeroy (1958) recommended that the typhimurium testing program of breeding flocks may be considered in areas where the disease is a problem. Serological tests in conjunction with bacteriological examination of cull chicks and poults will help to identify infected flocks. Müller (1957b) reported that in Denmark the selling of ducklings, goslings, and turkey poults hatched in incubators is allowed only when the hatching eggs originate from flocks in which no reactors to the *S. typhi-murium* and *S. enteritidis* tube agglutination tests have been found one month before the beginning of the hatching season.

Lee *et al.* (1936), Cherrington *et al.*

(1937), Pomeroy and Fenstermacher (1939), Hinshaw and McNeil (1943a, 1944a), Pomeroy (1944), McNeil and Hinshaw (1951), Delay *et al.* (1954), Pomeroy *et al.* (1957a), Ellis (1957), Lee (1957), Goetz (1962), and Yamamoto *et al.* (1962) have reported on the use of the agglutination test in turkey flocks. Hinshaw and McNeil (1943a) used a 1–25 dilution as a finding test and recommended that both a somatic (O) and flagellar (H) antigen be used to test each serum sample. Hinshaw and McNeil (1943b) used an H-type antigen to test turkeys for *S. newington* infection.

Delay *et al.* (1954) reported that 7,578 of 593,341 turkeys tested with *S. typhimurium* antigens by the tube agglutination method reacted in the diagnostic dilution of 1–25. Of this number, 4,486 were from flocks subsequently found to have *S. typhimurium* carriers. The O antigen was found to be most useful in detecting carriers, and birds revealing positive tests to both the O and H antigens were found most likely to yield *S. typhi-murium* on culture. They emphasized that a testing program for *S. typhi-murium* is most effective when it is possible to practice complete replacement of all flocks shown to harbor carriers of the organisms. Pomeroy *et al.* (1957a) also recommended that in a control program, based on the use of the agglutination test, reacting flocks should be disposed of, equipment and housing cleaned and disinfected, and replacement birds secured from a known clean source.

Belding and Mayer (1958) studied the use of the tube agglutination test to detect turkeys experimentally infected with *S. san-diego*. Only about one-third of the infected birds were detected by the test under the conditions of their experiment. Bierer and Vickers (1960a) found the rapid serum plate test using stained antigen for *S. typhimurium* to be superior to the tube agglutination test or the rapid whole-blood test in detecting turkeys demonstrated bacteriologically to be carriers of the organism. However, serological tests were not entirely effective in detecting the infection. Stover

(1961) pointed out that serological testing for *S. typhi-murium* in turkeys has helped to detect the infection in flocks that were subsequently disposed of or in which rigid sanitation including early heavy fumigation of eggs was applied. Yamamoto *et al.* (1961a) reported a positive correlation of 33.6 per cent between serological findings and isolation at 14 days after crop induced *S. typhi-murium* infection in adult turkeys. The percentage correlation had increased to 38.8 per cent at necropsy 35–44 days postinoculation. Yamamoto *et al.* (1962) found in Oregon that turkeys reacting as 3+ and 4+ to the agglutination test for *S. typhi-murium* had a higher isolation rate of the organism on culture. It was apparent, however, that a flock could not be considered infected on the basis of serology alone. Isolation rate on a flock or per-bird basis was optimum when 3 or 4 suspect birds were examined per flock. Serological testing was recommended merely as a part of the entire control program. Goetz (1962) described the role of the tube agglutination test for *S typhi murium* in the paratyphoid control program in California.

Schalm (1937), Buxton and Gordon (1947), Wilson (1948), Clarenburg and Romijn (1954), Gwatkin and Dzenis (1954), Gwatkin and Grinewitsch (1955a, b) and Sieburth (1957a, c) have reported the use of the agglutination test to detect carriers of paratyphoid infections in chicken flocks. Wilson (1948) indicated that the agglutination test is not likely to become a practical method for the detection of carriers of paratyphoid infections in chickens. Buxton and Gordon (1947) reported that in known infected flocks, the use of blood testing was believed to have merit as an adjunct to hygienic measures in the hatchery. Muller (1957a) used the agglutination test in examining 30,596 blood samples from ducks, geese, turkeys, and chickens from 1,356 flocks in the Danish islands. It was found that 26.4 per cent of the flocks contained reactors to *S. typhi-murium* and *S. enteritidis* antigens. Infection was confirmed by bacteriological cul-

ture in 41 of 361 reactors from 197 flocks. *S. typhi-murium* infected birds were found on one farm where the farmer and his family had experienced *S. typhi-murium* gastroenteritis.

Smyser and Van Roekel (1959), in the study of a supply flock to an institution where an outbreak of Salmonella food poisoning had occurred, serologically tested 5,050 chickens with the tube agglutination test for *S. typhi-murium*. Ninety-four reacting birds were detected, and 9 of the higher-titered reactors were cultured. *S. typhi-murium* was isolated from 2 birds. Müller (1961), reporting on the progress of the elimination of salmonellosis in poultry of the Danish islands, noted that more extensive serological testing programs should be conducted for *S. typhi-murium* infection.

Levine and Graham (1942) and Gordon and Garside (1944), among others, have reported on the use of paratyphoid antigens to test ducks. Lucas (1956) used furazolidone treatment and blood testing in the elimination of paratyphoid infection from mallard ducks. Perek and Rabinovitz (1957) concluded that agglutination tests of sera of geese for the detection of Salmonella carriers is of negligible value since agglutinins may be present for several types of Salmonella. Jungherr and Wilcox (1934) and Gauger *et al.* (1940) tested pigeons for paratyphoid, and Cunningham (1941) used serological procedures in an attempt to control paratyphoid infection in quail.

Various procedures have been recommended for the preparation of antigens for use in conducting serological tests for paratyphoid of poultry (Williams and MacDonald, 1955). The techniques usually employed in the United States for the preparation of tube agglutination antigen closely follow those recommended by McNeil and Hinshaw (1951), the Committee on Salmonellosis of the North Central Regional Poultry Disease Conference (Pomeroy *et al.*, 1957b), or the National Poultry and Turkey Improvement Plans

(Anon., 1963b). Yamamoto *et al.* (1962) also described methods for the preparation and standardization of *S. typhi-murium* antigen for testing turkeys. It is recommended that the O antigen is prepared from nonmotile cultures of the organism and the phase 1 and phase 2 H antigens from properly suppressed, motile cultures. The organisms for O antigen may be grown on beef heart infusion agar and harvested after incubation for 24–48 hours at 37°C. Organisms for the H antigen are cultivated on the above medium or in a liquid broth. The O antigen is harvested in a phenolized saline solution, and the H antigens are treated with formalin. Antigen suspensions are standardized and used in the same manner as pullorum tube agglutination antigen. The phase 1 and phase 2 H antigens are combined to make a single antigen before use. The tests with O antigen are incubated at 37°C. or 50°C. for 24 hours and tests with H antigen at 50°C. for 4 hours or 37°C. for 24 hours before reading. A diagnostic dilution of 1–25 is recommended for routine use. The O antigen is apparently more useful than the H antigen for the detection of carriers on initial tests.

Buxton and Gordon (1947) found that an alcoholized antigen is preferable to a heat-treated broth antigen in the detection of O agglutinins. Gauger *et al.* (1940) and Gwatkin and Grinewitsch (1955b) experimented with whole-blood antigens for the detection of *S. typhi-murium* infection in naturally and artificially infected fowl. Infected birds were not always detected by the antigens used. Clarenburg and Romijn (1954) using *S. bareilly* stained whole-blood antigen, were able to detect several infected birds; however, a large number of nonspecific reactions occurred with the antigen.

Blaxland *et al.* (1958) described the preparation and use of a stained, whole-blood *S. typhi-murium* antigen for testing chickens, turkeys, and ducks by the rapid, macroscopic plate method. The test with this antigen was found to be in close agreement with the tube agglutination test when dealing with birds revealing typically positive reactions. More nonspecific reactions were encountered with the *S. typhi-murium* stained antigen than with conventional *S. pullorum* plate antigens.

Harris and Williams (1957) demonstrated a bacterial hemagglutinin in 17 of 22 strains of *S. typhi-murium* examined. The hemagglutinin was heat labile and disappeared upon prolonged storage of cultures. The results of this study indicated the necessity of carefully selecting strains free of hemagglutinating activity for the production of diagnostic antigens that are to be used with avian whole blood.

Sieburth and Johnson (1956) and Sieburth (1957a, c; 1958b) have described an indirect hemagglutination test that may be of value in screening for the detection of *Salmonella* infections of poultry. Chicken erythrocytes sensitized with material liberated from boiled bacterial cells are used as the antigen in the test. A single polyvalent antigen was found to be capable of detecting several antigenic types of the infection. Hemagglutinins occurred in the blood of infected birds at a higher titer and appeared earlier than conventional agglutinins. It was stated that the indirect hemagglutination test, unlike the agglutination test, detected antibodies in chickens receiving furazolidone treatment. Sieburth (1960) further refined the antigen for the indirect hemagglutination test by developing methods for the production of more stable and standard antigen preparations.

Rice *et al.* (1960) applied the modified direct complement-fixation test for the detection of *Salmonella* antibodies in heat-inactivated turkey serum. Reactions recorded with partially purified somatic antigens were group specific. Magwood and Annau (1961) adsorbed crude and partially purified extracts containing *Salmonella* somatic antigens on polystyrene latex particles. The latex particles were used in agglutination tests to detect *Salmonella* agglutinins in turkey sera. The antigen revealed serological specificity and was agglu-

tinated by antibodies for the homologous Salmonella groups. Results with this testing procedure appeared encouraging, but the practical value of the test in naturally infected birds has not been determined.

In 1965 there was no official testing program for the control of paratyphoid infections on a nationwide basis. Heemstra (1952) pointed out the responsibility of the veterinary profession in helping the

poultry industry seek a solution to this problem. The application of serological procedures for the diagnosis of paratyphoid infections is dependent to a large degree on facilities available in state laboratories for conducting the tests. Furthermore, the importance of the paratyphoid problem in a particular area will indicate the desirability of using testing procedures as an adjunct to the general control program for the disease.

Arizona Infections

The Arizona group consists of motile, lactose-fermenting bacteria that conform to the general definition of the family Enterobacteriaceae. These organisms, also referred to as paracolon bacteria since their recognition in 1939, are closely related to members of the Salmonella and Citrobacter groups, but can be distinguished from them by biochemical tests and serological typing.

Edwards et al. (1959) and Edwards and Ewing (1962) have called attention to the vagueness and taxonomic inaccuracy of the term "paracolon infections" and do not support its further usage in modern bacteriological nomenclature. The term paracolon will be found at places in the following pages of this chapter in deference to its continued use by some and in the interest of accuracy of prior literature citations. As used here, it is not intended to denote a specific group of bacteria.

It was recognized early that there are no sharp limits to this intermediate group of organisms, and any classification that one might formulate must be open to a broad interpretation. Formerly paracolon bacteria have been accepted as occupying a position intermediate between typical coliforms and the paratyphoids, possessing certain characteristics of each. Most of the pathogenic organisms in the group were earlier thought to have the characteristic of fermenting lactose only after prolonged incubation.

The exact distribution, incidence, and

economic importance of Arizona infections have not been determined; however, the growing literature indicates that these infections are being encountered more frequently particularly among young turkeys. Hinshaw and McNeil (1946a), Edwards et al. (1956, 1959), and Goetz (1962) point out that Arizona infections pose a problem of considerable economic importance to the turkey industry.

ETIOLOGY

Stuart et al. (1943) and Borman et al. (1944) classified the paracolon organisms in a specific genus, Paracolobactrum, an appendix to the tribe Eschericheae, and recognized three species, namely Paracolobactrum aerogenoides, Paracolobactrum intermedium, and Paracolobactrum coliforme. This general classification was adopted by the seventh edition of Bergey's Manual of Determinative Bacteriology (Breed et al., 1957) with the addition of the species, Paracolobactrum arizonae.

In a second classification scheme, three main groups of paracolons were recognized with each group being composed of a large number of serologically and biochemically related members. These groups were designated Arizona, Bethesda-Ballerup (Kauffmann and Moeller, 1940; Stuart et al., 1943; Barnes and Cherry, 1946; Edwards et al., 1948d; Moran and Bruner, 1949; West and Edwards, 1954; and Lukas and Bradford, 1954), and Providence (Ewing et al., 1954)

Members of these groups that were pathogenic for poultry, other animals, and man were all included in the Arizona group which is the subject matter of this section. Bethesda-Ballerup and Providence paracolons were not found to be associated with disease outbreaks in poultry. In the discussion that follows, the former Bethesda-Ballerup paracolons are included in the Citrobacter group and the former Providence group is not discussed here as it has been placed with the Proteus group to which it is closely related (Edwards and Ewing, 1962).

Arizona group. In morphology and staining, members of the Arizona group resemble other enteric organisms. They are Gram-negative, nonsporogenic rods which are usually motile by means of peritrichous flagella. Most Arizona strains grow best at 37° C. and are facultative anaerobes with optimum growth under normal atmospheric conditions. The organisms can be readily cultivated on ordinary laboratory media, revealing an abundant growth similar to that of the paratyphoids. Many strains produce a putrid odor, although this characteristic is not consistent.

The first representative of the Arizona group was isolated from fatal infections of certain reptiles by Caldwell and Ryerson (1939). These investigators classified the organism as a *Salmonella* sp. (Dar-es-salaam, var. from Arizona). Kauffmann (1941), after a careful study of the flagellar antigens of one of the original cultures, designated the organism *S. arizona*. It was recognized that the Arizona culture fermented lactose and liquefied gelatin, and Kauffmann (1945) agreed that this organism should be classified separately from the Salmonella.

Investigations by Peluffo *et al.* (1942), Edwards *et al.* (1943, 1947, 1956, 1959), and Edwards and Ewing (1952, 1962) have indicated the biochemical and antigenic similarity, as well as the definite pathogenic properties of strains that make up the Arizona group.

Cultures possessing the following characteristics are almost invariably classifiable serologically as members of the Arizona group (Kauffmann, 1956; Anon., 1958b; Ewing and Edwards, 1960; and Edwards and Ewing, 1962):

Dextrose	— Fermented with gas
Lactose	— Fermented usually promptly
Sucrose	— Not fermented as a rule
Mannitol	— Fermented with gas
Maltose	— Fermented with gas
Dulcitol	— Not fermented
Salicin	— Not fermented
Sorbitol	— Fermented with gas
Adonitol	— Not fermented
Inositol	— Not fermented
Indol	— Not produced as a rule
Methyl Red	— Positive
Voges-Proskauer	— Negative
Simmons' Citrate	— Utilized
H₂S	— Positive
Urea	— Not hydrolyzed
Gelatin	— Liquefied slowly
KCN	— Negative as a rule
Nitrates	— Reduced
Motility	— Positive
Decarboxylases	
Lysine	— Positive
Arginine	— Positive usually delayed
Ornithine	— Positive
Malonate	— Positive
Phenylalanine Deaminase	— Negative

The majority of Arizona cultures ferment lactose promptly but some produce acid from lactose only after 7 to 10 days incubation. The procedures of sealing fermentation tubes with paraffin wax or serially passing the cultures in lactose broth hasten the fermentation of lactose. Edwards *et al.* (1956) reported that cultures of one serotype characteristically failed to ferment lactose. Occasional strains have been encountered which ferment sucrose rapidly, but these are the exception.

The majority of Arizona cultures grow very well on SS agar (Difco) as well as the other solid media recommended for the isolation of Salmonella. On initial isolation on these media, the colonies usually appear clear and colorless like the Salmonella, but may develop a pink or red color after continued incubation for several days or weeks. Rapid lactose-fermenting strains cannot be distinguished from normal coliforms, which are usually inhibited by these media. Mushin (1949) found desoxycholate

agar more effective than SS agar in the isolation of Arizona cultures from humans.

Felsenfeld and Young (1941) reported a medium containing 1 per cent each of lactose and sucrose, and one half of 1 per cent salicin in 0.3 per cent agar for the differentiation of paracolon bacilli and Salmonella. Chilton and MacDonald (1946), Colichon (1952, 1953), Sieburth (1957b), and Edwards and Fife (1961) have also described media for the differentiation of Salmonella and Arizona cultures. Bruner and Peckham (1952) reported the use of Selenite F as a liquid enrichment for the isolation of Arizona from poults.

Arizona strains are often mistaken for Salmonella since they are related so closely both biochemically and serologically; however, such errors are not of extreme importance since the organisms of both groups produce clinically identical diseases in poultry and prevention and control measures are the same for both. The failure of Arizona cultures to ferment dulcitol and their slow liquefaction of gelatin are most useful in distinguishing them from members of the Salmonella group. A summary tabulation of biochemical and other differential tests for identification of paratyphoid, Arizona, and Citrobacter strains is presented in Table 9.3.

Ellis et al. (1957) tested a total of 1,136 Salmonella and 621 Arizona cultures for their ability to utilize the organic acids D-tartrate, citrate, mucate, and malonate during an incubation period of 20 hours. Reaction patterns on these media were divisible into 2 groups, one of which was composed almost exclusively of Salmonella and the other essentially of Arizona strains. Edwards et al (1959) utilized these organic acids in further differential tests for Salmonella and Arizona strains. Especially useful for the purpose is the organic acid sodium malonate which is utilized (+) with Arizona strains and not utilized (−) with Salmonella cultures. Tests should be read after 24 and 48 hours (Edwards and Ewing, 1962).

Citrobacter group. For purposes of classification and identification, the Arizona group of bacteria must be differentiated not only from the Salmonella, but also from a second closely related group, the Citrobacter. Members of this group are not known to be pathogenic for poultry, but from a diagnostic standpoint may be confused with Salmonella and Arizona cultures on initial isolation from fecal specimens. The former Bethesda-Ballerup paracolons (Pc. intermedium) are included in the Citrobacter group along with cultures previously classified as Escherichia freundii. While members of the Citrobacter group are antigenically different from the Salmonella and Arizona groups they must be differentiated from them biochemically.

Members of the Citrobacter group are motile and usually ferment lactose; however, some cultures attack lactose slowly or not at all. Sucrose and salicin may or may not be fermented; indol is usually negative; gelatin is usually not liquefied; and dulcitol is usually fermented.

The potassium cyanide and ninhydrin tests are most valuable in distinguishing Citrobacter strains from those of the Arizona and Salmonella groups. Citrobacter strains grow in KCN medium while Arizona and Salmonella strains, as a rule, do not. Extreme caution must be taken in working with KCN medium to avoid its toxic effects to human beings. Citrobacter strains are ninhydrin negative while Arizona and Salmonella strains are positive. Procedures for conducting both the ninhydrin and KCN tests are described by Edwards and Ewing (1962).

ANTIGENIC STRUCTURE

Antigenically Arizona strains are similar to Salmonella and procedures for the serological study of both groups are identical. Members of the Arizona group have distinct antigenic characteristics that have afforded a means of antigenic analysis and grouping similar to that of the Kauffmann-White schema for Salmonella. Schiff et al. (1941) reported 1 indol-negative paracolon with the complete somatic antigens of S. onderstepoort and 4 others with all or a part of the somatic antigens of other

Salmonella. Edwards et al. (1948) isolated 1 paracolon culture with all the somatic and all but a minor flagellar antigen of a Salmonella type.

Sanders et al. (1945) and Burton and Garrard (1948) reported that atypical reactions observed in routine testing with S. pullorum antigen may be due to certain paracolon strains. The organisms may occasionally be recovered from the tissues of adult chickens and turkeys submitted for routine bacteriological examination as reactors to the blood test for pullorum disease (Gauger, 1946).

By examining the somatic and flagellar antigens of 382 Arizona cultures, Edwards et al. (1947) were able to demonstrate 25 O groups and 61 distinct serological types. Edwards et al. (1956) reported the examination of 1,308 cultures of Arizona among which 96 serotypes were recognized. Edwards and Ewing (1962) recognized 33 O antigen groups and 231 Arizona serotypes. In their diagnostic schema, the above investigators have designated both the somatic and flagellar antigens by Arabic numerals; thus, the original Arizona culture of Caldwell and Ryerson is designated antigenically as Ar. 0–1,2:H–1,2,5, or simply Ar. 1,2:1,2,5. This is the type species of the Arizona group.

Edwards et al. (1956, 1959) found serotype Ar. 7:1,7,8 to be more frequently isolated than any other type in the United States and reported that it comprised almost one-fourth of the total cultures studied and was isolated from 408 outbreaks of infection. In 1947 most of the outbreaks of Ar. 7:1,7,8 infection in poults were from eggs produced by a single cooperative turkey breeder association in a western state. This type is now found in turkeys in all parts of the United States. Moran (1959a) serologically typed 155 members of the Arizona group isolated from animals. A total of 138 of the cultures was isolated from turkeys and was confined to 2 serological types, namely 7:1,2,6 and 7:1,7,8. The number of each of these was approximately equal to the number of cultures of S. typhi-murium typed in 1957 from

turkeys, and combined was nearly twice as great. Arizona strains were not found to occur frequently in chickens. Moran (1960) reported the serological typing in 1958 of 119 Arizona strains, 74.7 per cent of which were isolated from turkeys and only 4.2 per cent from chickens. In 1959 the same author (Moran, 1961a) typed 91 Arizona cultures from chickens and turkeys, of which 93 per cent were isolated from turkeys and 7 per cent from chickens.

HOST DISTRIBUTION AND PATHOGENICITY

Edwards et al. (1947, 1956, 1959) have reported the isolation of Arizona strains from turkeys, chickens, canaries, ducks, parrots, a pheasant, a macaw, reptiles, swine, dogs, a mink, a cat, a Gila monster, a capybara, monkeys, guinea pigs, and opossums. Arizona cultures isolated from fowls and reptiles over a period of 20 years composed almost 75 per cent of the cultures studied. In 1939 when these infections were first recognized in turkeys, poults from individual hatcheries were found to harbor a single serotype of Arizona infection and it was possible to trace the source of the infection to certain hatcheries. Through the interchange of eggs and supply flocks this situation changed and infection with multiple types of Arizona organisms became the rule. The organisms were also recovered from man. Many of the cultures were from normal carriers.

Fey et al. (1957) discussed pathological changes encountered in 6 cases of Arizona infections of reptiles and described the biochemical and serological properties of the causative organisms isolated. Edwards et al. (1961) reported the isolation of 7 new Arizona types from reptiles. Like the paratyphoids, the Arizona organisms apparently recognize no host barriers, and are widely distributed in nature. Goetz and Quortrup (1953) reported the isolation of Arizona strains from gophers, and Hinshaw and McNeil (1947) cited lizards as carriers of the organisms.

Young chicks and poults are most frequently infected during the first 3 weeks

after hatching. Goetz and Quortrup (1953) recorded that the mortality rates among poults infected with Arizona 7:1,7,8 varied from 0.5 to 50 per cent, and occurred from the fourth or fifth day through the third week. Arizona infections in adult birds do not seem to be a problem, although such birds may serve as carriers of the organisms. Like the Salmonella, Arizona bacteria have a tendency to invade the blood stream and the mortality may be high (Edwards et al., 1956). Lewis and Hitchner (1936) reported the isolation of paracolon bacteria from young chicks suffering from an infection which simulated pullorum disease. The mortality rate ranged from 32 to 50 per cent in several broods which had been obtained originally from the same hatchery. These investigators were able to reproduce the disease under laboratory conditions in 1-day-old chicks by subcutaneous and oral inoculations. Guinea pigs were also found susceptible to the infection by parenteral inoculation.

Edwards et al (1947) demonstrated the pathogenicity of an Arizona strain by administering the organisms orally to a group of White Leghorn chicks. Deaths continued for 1 week with a mortality of 16.6 per cent. Of a group of Rhode Island Red chicks which were placed in the same pens as contacts, 26.6 per cent died. Arizona bacilli serologically identical with the organisms administered were recovered from the liver and intestines of every chick that died.

Perek (1957) isolated Pc. aerogenoides from a severe outbreak of paracolon infection in chicks in Israel. The organism proved to be highly infectious for chicks up to 4 weeks of age, but not for adult birds. Bigland and Quon (1958) reported 8 outbreaks of Ar. 7:1,2,6 infection in poults, chicks, and an adult hen in Alberta. This was the first time that Arizona infections had been found among poultry in Alberta. Mortality occurred up to 4 weeks of age and varied from 10 per cent in chicks to 50 per cent in poults.

Peluffo et al. (1942) and Edwards et al.

(1943) reported a group of Arizona strains which were isolated from poults as well as adult turkeys under natural conditions. Mortality varied from 15 to 60 per cent. The average mortality was 35 per cent. Cultures isolated from the same group of birds were of the same serological type and the birds had a common hatchery source.

Hinshaw and McNeil (1944b) reported the occurrence of Arizona type 8 as a cause of mortality in poults. They also reported the presence of this Arizona type in snakes found on the same premises and believed to be carriers of the infection. In further investigations Hinshaw and McNeil (1946a, b) isolated a number of cultures of Arizona serotype 7:1,7,8 from poults and snakes. On one ranch, where a 70 per cent mortality occurred, the greatest losses were observed during the first 5 weeks, but losses continued for 5 weeks. Gauger (1946) isolated Arizona 7:1,7,8 from an adult turkey.

Bruner and Peckham (1932) reported the isolation of Arizona 7:1,7,8 from an outbreak of Arizona infection in poults causing a mortality of 5 per cent. Galton (1953) isolated 13 cultures of Arizona type 10:1,2,5 in a poultry processing plant. Pomeroy et al. (1957a) reported the study of 120 outbreaks of Arizona infections in young turkeys. Four serotypes of Arizona were isolated. Serotype 7:1,7,8 was encountered most frequently. Edwards et al. (1959) found that the number of cultures isolated from turkeys greatly outnumbered those from chickens.

Dougherty (1953) cited two occasions on which he isolated Arizona organisms from duck livers revealing lesions very similar to those produced by paratyphoid infections. Edwards et al. (1947) indicated that Arizona bacteria may cause heavy losses among canaries in which the bacteria may be isolated from ocular tissues in cases of iritis. Edwards et al. (1959) reported that Arizona 13:13,14 was the only causative agent recognized in two highly fatal outbreaks of disease in canaries. Jones et al. (1932) described a type of paracolon encountered in many cases of infectious diar-

rhea in cattle. Johnson et al. (1951) reported infection of the bovine udder with paracolon bacteria. Ryff and Browne (1952) isolated a diphasic Arizona type (26:29,30) from aborted fetuses in ewes.

Reports dealing with the isolation of Arizona strains from man are numerous. Stuart et al. (1943) have indicated that these organisms are often associated with mild or acute gastroenteritis of short duration. Paracolons have also been associated with other pathological conditions in man including chronic enterocolitis (Luippold, 1947), pneumonia (Kraft, 1951), and endocarditis (Friedman and Goldin, 1949). Mushin (1949) found paracolon bacilli to be frequently associated with gastroenteritis of humans in Australia. Lystad (1962) studied 51 strains of Pc. acrogenoides responsible for a nasocomial outbreak of urinary tract infections in man. Evidence indicates that a cycle similar to that which exists between Salmonella infections in man and animals may exist with the Arizona group, and the importance of animals and animal products such as meat and eggs in spreading the infection to man must be considered. Galton (1956) and Edwards et al. (1956, 1959) reviewed the occurrence of cultures of the Arizona group in man.

MODES OF TRANSMISSION

Arizona infections are spread in a manner very similar to paratyphoid infections. Egg transmission of the disease in turkeys has been reported by Edwards et al. (1943), Hinshaw and McNeil (1946a), Edwards et al. (1947), Bruner and Peckham (1952), Goetz et al. (1954), Jamison (1956), and Edwards et al. (1956, 1959). Goetz et al. (1954) were able to isolate Arizona 7:1,7,8 from the eggs and embryos of turkey hens reacting to the agglutination test for this serotype.

Evidence has been presented to indicate that Arizona infection of a particular type may become established in a hatchery and then be spread to a distant establishment through eggs purchased from the original infected hatchery. Edwards et al. (1947) cited instances in which Arizona infection

with organisms of a certain serological type was traced from egg sources in California to points as far away as Minnesota, North Carolina, and Pennsylvania. Bigland and Quon (1958) suspected that Arizona infections were introduced with eggs shipped into Canada from certain western states of the United States. Edwards et al. (1959) in an epizootiological study of Ar. #10:1,2,5 infection in chickens traced the spread of the disease from a southern state to the Midwest and then back to the broiler producing areas of the Southeast. This same type of the organism has appeared in man, dogs, and cats.

Edwards et al. (1943) pointed out that Arizona infection may be carried for long periods by adult fowl which were infected as poults. Sadler et al. (1961) reported the isolation of 2 Arizona strains from intestinal samples of turkeys during a Salmonella survey. Jamison (1956) noted that since this disease usually started in poults in California in late April or May, it was suspected that the breeding flocks were infected from some outside source. Fecal contamination may spread the infection from other animal species to poultry. Goetz (1962) found an Arizona infection rate of 90 per cent in rats and 50 per cent in mice on the premises of a turkey ranch where the infection was a problem in poults. McClure et al. (1957) reported the isolation of several types of paracolon bacteria from the droppings of wild birds in the vicinity of Tokyo, Japan. No Salmonella was isolated from these specimens.

Hinshaw and McNeil (1946a) and Gauger (1946) reported the recovery of the organisms from the ovaries of adult turkeys. The frequent isolation of members of the Arizona group from egg powder by Edwards et al. (1947) suggested the wide distribution of the bacteria in chickens throughout the United States.

Arizona infections are transmitted in the incubator and brooder by direct contact and through contaminated feed and water. The role of contact in spreading the infection among chicks was illustrated by the experiments of Edwards et al.

(1947), already cited. Goetz et al. (1954) did not feel that Arizona infections are frequently transmitted to healthy poults during the brooding period. Erwin (1955) reported the isolation of 73 Paracolobactrum cultures during the bacteriological examination of 206 prepared poultry feed samples.

SYMPTOMS AND LESIONS

The symptoms and necropsy findings in Arizona infections of fowl simulate those of salmonellosis. While symptoms are not specific, infected birds may appear listless, develop diarrhea, and pasting of the down around the vent (Hinshaw and McNeil, 1946a). Bruner and Peckham (1952) reported that infected poults revealed signs of weakness, a tendency to rest on their hocks, ataxia, and trembling. Jamison (1956) reported nervous symptoms in Arizona infections of poults as a result of the organisms localizing in the brain. Perek (1957) observed that death from Arizona infection in chicks was accompanied by convulsions. Bigland and Quon (1958) noted that Arizona infections in chicks and poults revealed sudden deaths preceded for an hour or two by shivering, huddling, and anorexia. In birds 2-3 weeks old, diarrhea, droopiness, closed eyes, twisted heads, and evidence of blindness in one or both eyes were seen up to 2 days prior to death. Infected adults usually reveal no noticeable symptoms.

The lesions described by Lewis and Hitchner (1936) in chicks artificially infected with paracolon bacteria were typical of a generalized septicemia and included peritonitis; retained yolk sacs; enlarged yellowish, mottled or inflamed liver; and discolored heart. Similar lesions were noted in chicks by Edwards et al. (1947), and in poults by Bruner and Peckham (1952). Hinshaw and McNeil (1946a) found marked congestion of the duodenum, and ochre or mottled livers in Arizona-infected poults.

Eye lesions resulting in opacity and partial or complete blindness seem to be quite common in some types of Arizona infections in poults. Jamison (1956) called attention to the cloudiness of the eyes in infected poults which is also observed in Newcastle disease. The organisms can be readily recovered from the infected eye tissues. Bigland and Quon (1958) described eye lesions as a common occurrence in Arizona infections. They found a heavy, yellowish-white, cheesy exudate covering the retinae. Affected eyes became quite desiccated and failed to grow normally. Other lesions included distention of the gallbladder, caseation of the ceca, and tiny lung abscesses. Hinshaw and McNeil (1946a) reported the recovery of Arizona organisms from adult turkeys, two of which had small, caseous mesenteric lesions and three had cystic ovules.

Histological changes due to Arizona infection of chicks were observed by Perek (1957) as fatty degeneration of the liver and distinct capillary congestion of the kidneys.

DIAGNOSIS

Symptoms and lesions are of little value in differentiating Arizona infections from paratyphoid or pullorum disease. Findings on necropsy must be substantiated by recovery and identification of the causative bacteria. In Arizona infections the organisms can usually be recovered from the liver, heart blood, lungs, kidneys, unabsorbed yolk, and intestines. Bigland and Quon (1958) were able to readily isolate Arizona strains from the caseous material covering the retinae of affected eyes. They called attention to the need to differentiate this infection from that due to Aspergillus fumigatus when eye involvement occurs.

Cultural procedures identical to those for paratyphoid infections are employed. Moran (1959b) has reported procedures and media for the isolation and identification of Arizona strains from fresh specimens. The history of the outbreak, as well as the degree of infection indicated by culture results, must be taken into consideration. Recovery of the organisms from the intestinal tract alone may be of little significance. Goetz and Quortrup (1953) used

the cloacal swab and culture technique in an effort to detect carriers of Arizona organisms in adult turkey flocks which had suffered a severe outbreak as poults. Results were entirely negative.

Arizona organisms may be discarded as coliforms, and many probably are. When extended incubation is not practiced, they may be classified as Salmonella strains on initial isolation. The mounting evidence of the pathogenicity for fowl of members of the Arizona group indicates the necessity for studying this group of organisms more closely. Typical reactions of Arizona cultures on selected diagnostic media are listed in Table 9.3. Edwards and Fife (1961) described a lysine-iron agar for the detection of Arizona strains that rapidly ferment lactose. Salmonella and Arizona strains produce a distinctive reaction as they regularly form lysine decarboxylase rapidly and produce large amounts of hydrogen sulfide. Serological analysis of cultures is essential in epizootiological studies of Arizona infections of fowl. If facilities for complete identification of the organisms are not available, cultures should be submitted to the U.S.D.A.'s Diagnostic Services, National Animal Disease Laboratory, Box 70, Ames, Iowa, where the cultures may be studied more closely biochemically and typed antigenically. Goetz et al. (1953) reported the use of a polyvalent antiserum in screening cultures that were suspected to be Arizona strains.

TREATMENT

The use of chemical therapeutic measures may reduce losses in acute outbreaks of Arizona infections, and may be recommended to prevent the spread of the disease in market flocks. Hinshaw and McNeil (1946a) in their study of Ar. 7:1,7,8 infection of turkeys reported the administration of sulfamerazine to a group of 8-day-old poults that had suffered a 12 per cent mortality previous to this treatment. The drug was used at a dosage of 0.25 per cent in the mash for 3 days. Marked improvement was noted in the treated group as compared to untreated

controls. Cessation of treatment resulted in increased losses. A favorable response was noted when the same treatment was administered to both groups of birds for 3 more days. When the survivors were tested with the agglutination test 6 months later, no reactors were found. Goetz et al. (1954) reported that the use of various combinations of sulfonamides and antibiotics had little effect upon mortality from Arizona infections of poults.

Harwood (1956), Jamison (1956), and Pomeroy et al. (1958) have reported on the use of furazolidone (nf-180) in the treatment of Arizona infections. Jamison (1956) described the experimental use of furazolidone in the feed of adult turkey flocks in California as a preventive against Arizona infections. It was recommended that 100 grams of the drug be added to each ton of feed for 1 week each month. The same level of the drug for 5 to 7 days was recommended in treating acute outbreaks of the disease in poults. This level of treatment was also suggested for the first 2 weeks of brooding as a preventive in poults from breeding flocks suspected of having Arizona infections. Higher levels of furazolidone may be recommended and prove more effective in treating particularly severe outbreaks. It is possible that treated birds may remain intestinal carriers of the causative organism. Harwood (1956) has suggested the use of a combination treatment consisting of a sulfonamide in the drinking water and furazolidone in the feed for treatment of severe outbreaks of the disease.

Pomeroy et al. (1958) found that furazolidone fed to poults at a level of 100 grams or higher per ton reduced the mortality from Arizona infection 50 per cent when administered at the time the poults were experimentally exposed to the organisms. The 200 gram per ton level of the drug was found to be more effective in reducing poult mortality and in eliminating Arizona isolations from surviving birds. When the treatment was started before exposure, the 100 gram per ton level of the drug was found to have a preventive effect

on development of the disease. Goetz (1962) reported that intensive furazolidone treatment of laying turkeys infected with Arizona did not eliminate the presence of the organisms in the eggs of such turkeys.

PREVENTION AND CONTROL

Since Arizona infections of fowl are transmitted in the same manner as paratyphoid infections, the control program for this disease is identical to that for paratyphoid infection as outlined earlier in this chapter.

Jamison (1956) found Arizona bacteria more resistant to formaldehyde fumigation than *S. pullorum*. It was recommended that eggs suspected of carrying Arizona organisms should be fumigated with 3 times the amount of formalin-potassium permanganate mixture used to fumigate for pullorum disease. Fumigation should start as soon as the eggs are set and the temperature and humidity are up to regular operating levels. Eggs should never be fumigated between the 24th and 96th hours of incubation. It was recommended that the eggs be fumigated again with the triple strength fumigant just before they are transferred to the hatching trays. If continuous fumigation is used, the regular level of the fumigant was suggested.

Because of the large number of antigenic types of Arizona strains, any control pro-

gram involving the use of the agglutination test to detect infected adults must be based on the location and disposal of infected breeding flocks. Specific types of antigen must be prepared and used in each case. From the small percentage of reactors to the agglutination test found by Hinshaw and McNeil (1946a), it would appear that the infection may be more easily shed than is pullorum disease. Goetz *et al.* (1954) used an experimental plate agglutination antigen to test serum samples from turkey flocks infected with Arizona 7:1,7,8. In one flock containing 1,414 birds, 6 reactors were found, 5 of which yielded Arizona on culture. A retest of the flock 1 month later revealed no reactors. Other flocks tested contained many reactors and were disposed of. Goetz (1962) described the use of a flagellar tube agglutination test for Arizona infection in California turkeys. Reference may be made to the section on Prevention and Control of paratyphoid infections for a discussion of the California program for the control of Arizona infections in turkeys.

The establishment of the Arizona as a group of considerable pathogenic importance for fowl suggests that all efforts aimed at the prevention and control of paratyphoid infections must also take into consideration these closely related organisms.

Fowl Typhoid

Fowl typhoid is a septicemic disease of domesticated birds. The course may be acute or chronic. The mortality may be moderate or very high, depending largely on the virulence of the inciting organism, *Salmonella gallinarum*. It appears to be primarily a disease of chickens, but in exceptional cases ducks, turkeys, pheasants, peacocks, guineas, and a few other birds are attacked.

History. In 1888 a chicken breeder in England lost 400 chickens as a result of an infectious disease which was at first considered to be fowl cholera. Two hundred of these birds died in the first two months of the outbreak. Specimens were sent to Klein (1889) for necropsy and diagnosis. He reported it chiefly as an infectious enteritis. The intestinal mucosa and serosa were inflamed, and the feces appeared thin and greenish yellow. The spleen was enlarged two to three times; the liver was also somewhat enlarged, soft, flabby, and moist. The cause was an organism which he

named *Bacillus gallinarum*. The same year he reported the disease among grouse, and in 1893 a similar disease among pheasants. The disease was investigated by Smith in Rhode Island in 1894 and more fully by Moore in Virginia and Maryland in 1895. Moore (1895) described the disease as "infectious leukemia" and named the organism *Bacillus sanguinarium*.

Klein observed small numbers of bacilli in the blood. They were nonmotile, Gram-negative, and were easily cultivated. Chickens inoculated subcutaneously became sick in 5 to 6 days and died 2 to 3 days later. A similar disease was described by Lucet (1891) in France. Lignières and Zabala (1905) described a disease which was probably identical with Klein's disease. The catarrhal enteritis and the swollen spleen attracted attention; Gram-negative bacilli were observed in the blood. They were different from those described by Klein in that they first coagulated, and later peptonized, milk with an alkaline reaction.

[329]

Curtice (1902) studied the disease in Rhode Island and named it "fowl typhoid." The disease has been found in Germany, Hungary, Austria, France, Holland, and North and South America, as well as in Algiers. In Germany it was observed by Pfeiler and Rehse (1913) Van Straaten and te Hennepe (1918) in Holland described the disease very fully.

On the basis of the post-mortem observation, Klein believed that it was not cholera, but a special disease. His suspicion was soon confirmed, because he ascertained that the newly discovered organism was different morphologically and biologically from that of fowl cholera.

Transmission. Like most other bacterial diseases, fowl typhoid is spread in several ways. Research on the transmission of fowl typhoid indicates that the infected bird, the reactor and carrier, is by far the most important means of perpetuating and spreading the disease. Such birds may infect not only their own generation but succeeding generations through egg transmission.

Evidence of egg transmission of *S. gallinarum* was reported by Beaudette (1925, 1930), and by Beach and Davis (1927).

Nobrega and Bueno (1942) cultured 1,465 fresh, infertile eggs from 52 hens shown to be chronic carriers of fowl typhoid. These were reactors from three different flocks where severe outbreaks of fowl typhoid among chicks had been experienced. The incidence of *S. gallinarum* in the eggs from the three lots of fowls was 2.8, 0, and 1.73 per cent, respectively.

Moore (1946a) recovered *S. gallinarum* from 8.9 per cent of 395 eggs cultured from a pen of 21 fowl typhoid reactors, some naturally and some artificially infected. He also conducted fowl typhoid transmission experiments with flies, turkey buzzards, rats, and also by mating and by air currents. No evidence was produced to indicate transmission of the disease by flies, by mating, or by air currents. Rats and turkey buzzards were found capable of transmitting fowl typhoid. Boney (1947) isolated *S. gallinarum* from one turkey egg

of 374 cultured from a flock of pullorum reactors.

Gordeuk et al. (1949) found that fowl typhoid is transmitted from artificially infected birds to normal fowls by cohabitation. The mortality among normal birds was 60.9 per cent in one group and 45.8 per cent in another. In other exposure trials by contamination of feed or drinking water with a broth culture of *S. gallinarum* or with feces from fowl typhoid infected hens, mortality among normal pullets varied from 31.8 per cent to 69.6 per cent in four experiments with duplicate groups.

After culturing over 10,000 eggs from two flocks, one naturally infected and one artificially infected, Hall et al. (1949a) found that 50 per cent of typhoid reactors laid infected eggs, and an average of 6 per cent of all unhatched eggs were infected with *S. gallinarum*. That these infected eggs laid by typhoid carriers are highly virulent and may be the means of starting new outbreaks of fowl typhoid in laying flocks is indicated by six feeding trials in which 27 birds ranging in age from eight weeks to one year were fed one or more infected eggs mixed in their mash, with death resulting in all but six in an average period of ten days. These investigators also report that of 906 chicks hatched from these reactors 296, or 32.6 per cent, died of the disease during the first six months with the heaviest loss in the first month.

Rao et al. (1952) recovered *Salmonella gallinarum* from 13 of 36 (36 per cent) eggs from a reactor flock.

Jordan (1956a) recovered, by a single swab, *Salmonella gallinarum* from the fresh feces of 4 of 13 birds acutely ill of fowl typhoid. Single cloacal swabs were positive in 15 of 47 (31.9 per cent) similar birds and were positive in blood cultures in 44 of 47 (93.6 per cent). A total of 377 cloacal swabs were taken at intervals from 36 reactors which had recovered from fowl typhoid 3 to 18 months previously, but only one bird was positive for *S. gallinarum*.

Jordan (1956b) reported isolation of

Salmonella gallinarum from eggs laid by reactors to the rapid blood test:

From 3 of 23 eggs (13 per cent) from 4 recovered birds.

From 13 of 274 eggs (4.75 per cent) from 10 naturally recovered birds.

From none of 217 eggs from 4 birds, treated with Chloromycetin, that had recovered from fowl typhoid.

From 25 of 226 eggs (11 per cent) from 2 recovered birds that received nitrofurazone.

Both *S. pullorum* and *S. gallinarum* were isolated from different eggs from one bird.

Attendants, feed dealers, chicken buyers, and visitors who travel from house to house and from farm to farm may carry the infection unless precautions are taken to disinfect footwear, hands, and clothing. Trucks, crates, and feed sacks are also important. Wild birds, animals, and flies may be important mechanical spreaders, especially if they have been feeding on carcasses of dead birds, or on offal from packing plants or hatcheries.

Distribution. The disease is widespread in the poultry-producing areas of the country, but outbreaks are sporadic, depending on factors which are not completely recognized at present. The distribution changes from year to year and season to season, although the seasonal variation seems to be more marked in the northern than in the southern parts of this country.

In a nationwide survey Moore (1916b) found fowl typhoid to be most prevalent in the eastern states. Nineteen states reported fowl typhoid to be increasing during the preceding five-year period. This was especially noticeable in the Atlantic seaboard states. The survey showed fowls of all ages and breeds to be susceptible, including chickens, turkeys, and guineas. Moore also found fowl typhoid to be most prevalent in Delaware in the summer and fall. Twenty-one states in the survey reported similar observations. Two states reported it to be more common in winter, while eight states had not found the disease to be seasonal. Hall *et al.* (1919a) found that the curve of fowl typhoid infected egg production varied directly with the total egg production and for that reason outbreaks of fowl typhoid tended to be seasonal.

According to reports from Europe, it is now more widespread than before the first World War, although there has been a steady decline in incidence during the past ten years. Truche (1923), in France, and te Hennepe and van Straaten (1921), in Holland, report the disease as most prevalent in the spring and early summer.

According to Hall (1916), fowl typhoid has become much more prevalent in eastern United States during the past few years. It is especially severe in some broiler-raising areas. He reports that birds of all ages, from baby chicks to breeding hens, are affected, and the disease occurs with equal frequency in young and mature stock. Losses range in outbreaks from an occasional bird in old breeding flocks up to 75 per cent or more in younger fowls.

Glover and Henderson (1946) report an outbreak in chickens in Canada and state that it is believed to be the first case reported in that country.

Bigland (1951) reported an increase of fowl typhoid in Alberta from two cases in 1918 to 37 cases in 1952 in the east central part of the province. The spread was attributed largely to poor sanitation in poultry management.

Etiology. The causative agent of fowl typhoid is a relatively short, plump rod about 1.0–2.0μ long and 1.5μ in diameter. It has received the following names: *B. gallinarum, B. sanguinarium, B. typhi gallinarum alcalifaciens, B. paradysenteriae gallinarum, Eberthella sanguinaria, Shigella gallinarum,* and *Salmonella gallinarum.*

The bacilli mostly occur singly but are occasionally united in pairs. They have a tendency to stain a little heavier at the poles than in the center. They are Gramnegative, form no spores and no capsules, grow aerobically, and are nonmotile.

Gelatin colonies: Small, grayish-white, entire.

Gelatin stab: Slight, grayish-white sur-

TABLE 10.2
SUMMARY OF CHARACTERISTICS OF VARIANTS OF *Salmonella pullorum*
AND *Salmonella gallinarum* (HINSHAW, 1941)
Fermentation Reactions

S. gallinarum (Duitburg) (2 cult.) . . .	A	‡ or A	A	A	—	A

AG=acid and gas, A=acid, ‡=variable or slow reaction; T=yellowish-white or grayish turbidity in media.
* No maltose fermenting strains were isolated in Kansas.

is stronger with *S. pullorum* than with *S. gallinarum*, and Klimmer and Haupt (1927) state that the reverse is true. Pacheco and Rodrigues studied the reactions on a variety of media with lead acetate, bismuth with and without cysteine, iron salts, and a peptone gelatin. *S. pullorum* produced H₂S rapidly on agar with lead and bismuth, both with and without cysteine, and slowly on the other media.

Hinshaw (1941) was able to separate the two species by use of a 0.15 per cent cysteine hydrochloride gelatin medium. *Salmonella gallinarum* in 89 of 91 strains produced a characteristic yellowish-white or grayish turbidity when incubated at 37° C. for 72 hours. *S. pullorum* did not produce such changes. Several maltose-fermenting variants of *S. pullorum* have been observed among those studied. None of these gave a positive reaction either in the cysteine-gelatin medium or in tartrate agar. He concludes that although many

variants exist, there is increasing evidence that these organisms are a distinct species.

Hinshaw reports that H₂S can be demonstrated readily in cultures of *S. gallinarum* growing in cysteine-gelatin by its faint odor and by use of strips of lead acetate paper. Only a faint browning of such paper is noted in *S. pullorum* cultures grown in this medium.

Table 10.2 contains a summary of the characteristics of variants of *S. pullorum* and *S. gallinarum*.

It is stated that there are probably several subspecies in the *pullorum-gallinarum* group. The Van Roekel maltose-fermenting strain gave reactions identical with those of the California maltose-fermenting strains. These strains differ from the *Salmonella intermedius* A-type strains in that the latter are xylose-negative and dulcite-positive. The *S. intermedius* B-types were sensitive to *S. pullorum* bacteriophage and were considered by Nobrega (1935) as

variants of the latter organism. Hinshaw (1941) found that *S. intermedius* A and B types reacted like *S. pullorum* in both cysteine-gelatin and tartrate agar. He states that the maltose-negative strain of *S. gallinarum* of Van Roekel was so classified on the ground that it produced a positive *S. gallinarum* reaction in cysteine-gelatin, acid in tartrate agar, and was dulcitol-positive.

The dulcitol-negative *S. gallinarum* of Kujumgiesff differs from that of Delpy and Rastegar's (1938) type B, in that the latter is dulcitol-positive and tartrate-negative.

The Duisburg strains of *S. gallinarum* are like *S. pullorum* in that they do not ferment tartrate agar and do not give any reaction in cysteine-gelatin. They resemble *S. gallinarum* in the type of growth on nutrient agar, and in being maltose- and dulcitol-positive. They are more nearly like the *S. intermedius* type B.

Johnson and Rettger (1942) studied the basal nutrition of *S. gallinarum* and *S. pullorum* with sixteen amino acids and thioglycolic acid. With the exception of two strains which required nicotinic acid or its amide, 43 strains of *S. pullorum* did not require any vitamins, while vitamin B_1 proved to be highly indispensable for the growth of 22 strains of *S. gallinarum*. Nearly all strains of *S. pullorum* required glucose while *S. gallinarum* did not. None of the strains of the former required the addition of CO_2, while several of the latter required an appreciable amount for growth. Leucine was the most important single amino acid; tryptophane was not required.

Although there are certain cultural and physiological differences between *S. gallinarum* and *S. pullorum*, their serological and antigenic characters are identical. Some European investigators are of the opinion that chronic *S. pullorum* infection and fowl typhoid are two forms of the same disease. This opinion is not generally held in the United States. Rettger and Koser (1917) concluded as early as 1917 that despite the several characteristics which these organisms have in common,

and particularly the serological reactions, the organisms constitute two distinct types, and each holds a specific relationship to the disease with which it has been associated in the past.

Beck and Eber, Beaudette, Hadley *et al.*, Hendrickson, Mulsow, May, Goodner, Rettger, Koser, Manninger, van Heelsbergen, and others have tried to separate the *S. gallinarum* and the *S. pullorum* on the basis of the agglutination reactions but have not succeeded. Even by applying the absorption method, the two organisms proved to be identical. Kauffmann (1930, 1931) states that *S. gallinarum* and *S. pullorum* strains contain the same O-antigen. This has been confirmed by Edwards (1939) in more recent studies. Many investigators consider that it is not improbable that *S. gallinarum* and *S. pullorum* represent two varieties of one microorganism. (See particular description under pullorum disease.)

Rodrigues and Pacheco (1936) were unable to detect any antigenic difference between *S. gallinarum* and the intermediate types. Although some appear to doubt that it is worthwhile to differentiate between the organism of fowl typhoid and pullorum disease, most American investigators agree that the organisms are somewhat different in their fermentation reactions and the pathological changes which they produce in infected birds. The agglutination test will not differentiate between carriers of either type of infection. Hinshaw (1941) was able to differentiate the two organisms by the use of a 0.15 per cent cysteine-hydrochloride gelatin medium first reported by Hinshaw and Rettger (1936). After incubation at a temperature that does not liquefy the gelatin, a turbid halo appeared around the individual colonies in shake cultures and along the line of inoculation in stab cultures. None of the 454 strains of *S. pullorum* consistently produced visible change in the medium, or at best a surface pellicle. Species of bacteria which were irregular in their reactions, but which gave mostly negative results were 14 strains of *E. typhi*

and 3 strains of *S. anatum*. A few cultures of Pseudomonas and Proteus from turkeys gave these reactions.

The Jordan-Harmon sodium-potassium-tartrate medium (1928) was a valuable supplementary medium to use with the cysteine-gelatin. The *S. gallinarum* strains consistently produced acid on this medium while *S. pullorum* produced no change.

Blaxland et al. (1956) made a study of the differential characteristics of 1,007 cultures of *Salmonella pullorum* and 618 cultures of *Salmonella gallinarum*, based on growth characteristics, biochemical reactions, and the absence of form variation in *S. gallinarum*. These differences are related to the distinctive epizootiology of acute outbreaks of pullorum diseases and fowl typhoid as occurring in the field.

It is considered that the results, taken in conjunction with the work of earlier investigators, provide conclusive evidence that *S. pullorum* and *S. gallinarum* are separate and distinct species.

Williams and Harris (1956) compared 41 strains of *Salmonella gallinarum* and 23 strains of *Salmonella pullorum* by the sedimentation test, using ammonium sulfate, and found that an ammonium sulfate concentration of 265 grams per liter completely cleared the supernatant fluids of most *S. gallinarum* suspensions but had considerably less effect on the turbidity of suspensions of standard cultures of *S. pullorum*. These observations suggest that there may exist minor antigenic differences between *S. gallinarum* and standard strains of *S. pullorum* that are not demonstrable by conventional serological methods.

Goret et al. (1956) discuss the similarities of *Salmonella gallinarum* and *Salmonella pullorum*. Usually the term "fowl typhoid" is used to describe a disease of adult chickens due to *Salmonella gallinarum*. "Pullorum disease" is used to describe a septicemia of embryos and chicks due to *Salmonella pullorum*. This distinction is erroneous. Septicemic conditions may be produced by either organism and chronic typhoid lesions are produced by gallinarum and pullorum types. When *S.*

gallinarum and *S. pullorum* are studied serologically, it is found that both have identical serological antigens. All strains contain the I, IX, and XII antigens; none of the strains contain XII₂ antigen. Both organisms show considerable variation in fermentative reactions—*S. gallinarum* may be grouped into seven distinct classes and *S. pullorum* into nine classes. Lysogenic studies show that both organisms are identical in their phage reactions. *Salmonella gallinarum* and *S. pullorum* should be considered as one species—*Salmonella gallinarum-pullorum*.

Ishii et al. (1958) examined 225 non-motile strains of Salmonella Group D isolated from chickens, and found that if *Salmonella pullorum* and *S. gallinarum* were considered as two distinct types, then the characteristics differentiating them seemed inconsistent and variable. The epizootiological distinction between the two organisms emphasized by earlier workers was not confirmed. It was further considered that too frequent occurrence of interrelated cultures threatened the significance dividing the organisms into two types.

It was also stated that it is against the rule of classification of enteric bacteria to divide the organisms into two types by biochemical methods. Therefore, it was recommended, as stated by Kauffmann, that the organisms be classified into a single type, "S. gallinarum-pullorum," and that the conventional classification be regarded as biotypes without special names.

Trabulsi and Edwards (1962) studied the biochemical characteristics of *Salmonella pullorum* and *Salmonella gallinarum*, as well as those of several aberrant cultures of Salmonella Group D. In addition to the tests usually used to differentiate *S. pullorum* and *S. gallinarum*, the cysteine-gelatin medium of Hinshaw and the ornithine decarboxylase test were found valuable in distinguishing the two types. It was concluded that *S. pullorum* and *S. gallinarum* constitute two distinct biochemical types which should not be

joined. The rare occurrence of aberrant strains which probably are neither *S. pullorum* nor *S. gallinarum* should not be permitted to confuse the problem.

Resistance. In general the resistance of this organism is about the same as that of the other members of the typhoid and paratyphoid groups.

The fowl typhoid organism is killed within 10 minutes at 60°C. It remains viable in the dark for 20 days in ordinary and in distilled water, but dies in 24 hours when exposed to sunlight. When dried on glass plates and kept in the dark, the organism retains its viability for 89 hours; under the action of direct sunlight it is killed in a few minutes. The organism is killed by phenol in a 1:1,000 dilution and by bichloride of mercury in a 1:20,000 dilution, potassium permanganate 1.0 per cent in 3 minutes, and 2.0 per cent formalin in 1 minute. Agar cultures rapidly lose their pathogenic character, although they retain their antigenic properties for some time. According to Altara, *S. gallinarum* in the virulent state can be demonstrated in the bone marrow of carcasses three months after chickens have died of fowl typhoid. No doubt under certain conditions it lives for much longer periods. Kaupp and Dearstyne (1924a) reported that although direct sunlight destroyed the organism in a short time, it remained viable for 20 days when stored in water in the dark.

In Moore's (1946b) national survey of fowl typhoid, 75 per cent of the states reporting were uncertain as to the persistence of the organism in the soil, and 25 per cent claimed that it persisted from year to year.

In the experiments of Hall *et al.* (1919a) there was little danger of starting an outbreak in susceptible birds when such birds were put into a fowl typhoid-contaminated pen one week or more after removal of all sick birds. It was evident that the causative organism did not survive long after leaving the bird's body.

The resistance of this organism to the action of bacteriophage is of some interest.

D'Herelle (1919, 1922) examined the excreta of fowls and tested the bacteriophage for virulence against eight strains of bacteria. Bacteriophage activity was demonstrated from all excreta studied; some samples showed marked activity for all cultures used. This investigator claimed that his experiments with bacteriophage confirmed his conclusion that the immunity to an infection is assured at a time when the body contains a bacteriophage virulent for that organism. Mallmann (1931a) criticizes these observations because of lack of controls. It was found that the bacteriophage from one organism was easily adapted to another by use of mixed cultures. Bacteriophage was of no value in treating chicks either naturally or artificially infected. Munné (1937) obtained several cultures of *S. gallinarum* and *S. pullorum*, all of which were equally susceptible to the action of bacteriophage.

In two experimental and one natural outbreak of fowl typhoid, Hall, MacDonald, and Legenhausen (1919b) saw no benefit from the administration of bacteriophage either in the drinking water or by subcutaneous experimental outbreak or by subcutaneous injection in the natural outbreak.

Orr and Moore (1953) tested *Salmonella gallinarum* for longevity under various conditions. In cloth in the dark at room temperature the organisms remained alive for 228 days. On plastic cover slips some *S. gallinarum* organisms were viable up to 93 days. Organisms in distilled water in diffused light at room temperature were viable up to the time the water evaporated –88 days. *S. gallinarum* retained viability up to 43 days when subjected to daily freezing and thawing. A liver naturally infected with *S. gallinarum* was divided, one-half being kept at 7°C., and the other half at –20°C. The organisms in the liver kept at 7°C. survived two weeks, while those in the portion of liver kept at –20°C. were still alive at 148 days, even though they were twice accidentally thawed.

Smith (1955a) found that the average survival time of *Salmonella gallinarum* in

feces from infected chickens was 10.9 days when kept in a range house and 2 days less in the open. Survival time was longer in naturally dried specimens than in those kept moist.

Pathogenicity. The pathogenicity of fowl typhoid cultures has proved decidedly variable in the hands of different investigators, probably for the reason that they used cultures varying widely in virulence. Like most pathogenic microorganisms *S. gallinarum* loses virulence rapidly on artificial media. Hence, cultures of *S. gallinarum* should be passaged serially in their natural host, the chicken, before testing the pathogenicity of the organism. The pathogenicity of such cultures is best maintained in the lyophilized or frozen state. With a *uniformly pathogenic culture, most commonly used routes of exposure of chickens prove fatal.* Kaupp and Dearstyne (1925) reported 16 deaths out of 40 chickens artificially infected; 15 became visibly sick, and 9 showed no symptoms. Similar results were reported at the Kansas Station, whereas others report from 25 to 90 per cent loss.

Palmer and Baker (1928) studied six natural outbreaks of fowl typhoid on Delaware farms. Virulent strains from these outbreaks killed not over 33.3 per cent of the test fowls, and the investigators concluded that 60 to 70 per cent of fowls are naturally immune. Hall, Legenhausen, and MacDonald found that feeding mash moistened with a broth culture of a stable virulent strain of *S. gallinarum* was an effective way of testing susceptibility to fowl typhoid. Of 20 groups of birds, aggregating 382, which were challenged by adding a broth culture of virulent strains of *S. gallinarum* to their mash, 367, or 96 per cent, died of fowl typhoid.

Although fowl typhoid frequently has been spoken of as a disease of adult birds, Beaudette (1925), Beach and Davis (1927), Martinaglia (1929), and Komarov (1932) reported the disease in young chicks. Moore (1946b), in a nationwide survey of fowl typhoid, reported that 11 states found the

disease to be more common in birds under six months, 16 believed the disease to be more prevalent in older fowl, while 10 states reported that there was little difference in age susceptibility. Hall *et al.* (1949a) reported that in 25 hatches from typhoid reactors in their second year of lay, about every fourth hatch experienced a fowl typhoid outbreak and losses up to six months of age amounted to 33.4 per cent of the chicks hatched. Monthly distribution of mortality was as follows:

Month	Per Cent
1	25.6
2	13.5
3	24.9
4	19.2
5	13.8
6	2.7

As in pullorum disease, fowl typhoid losses often begin at hatching time; but contrary to experience with pullorum disease, fowl typhoid losses continued through to laying age. In one experiment in which two lots of chicks were hatched from fowl typhoid reactors, 92.8 per cent of the chicks hatched in one lot died within 16 days and in another lot 93.5 per cent died within 11 days after hatching.

Epizootiologically there are a few peculiarities in regard to the disease. Van Heelsbergen (1929) states that according to his experience it is very difficult, in some cases at least, to infect chickens which come from a region to which fowl typhoid is indigenous. If chickens are imported from a part of the country where the disease is not known, infection is rather easy. It is suggested that the bacteriophage, or acquired immunity, is probably in part responsible.

St. Johns-Brooks and Rhodes (1923) found that strains of *S. gallinarum* produced lesions in young chicks indistinguishable from those associated with pullorum disease.

A relatively small number of avian species appear to be susceptible. Lucet (1891) described what was probably an

outbreak of the disease in turkeys but claimed that ducks, geese, and pigeons were not susceptible. Donatien et al. (1923) consider palmipeds to be refractory, but found the turkey, guinea fowl, and peafowl among the susceptible species; ducks and geese were resistant. Pfeiler and Roepke (1917) mention the pheasant, turkey, and guinea fowl as susceptible in natural outbreaks, but that ducks, geese, and pigeons are not, although a duck which had been inoculated with a culture died a few days later. Kaupp and Dearstyne (1924), Beck and Eber (1929), and te Hennepe (1924) have observed the disease in ducks. Kaupp and Dearstyne (1925) state that turkeys are less susceptible than chickens, and that guineas, though slightly susceptible, yield to artificial inoculation. Fox (1923) isolated B. sanguinarium from an outbreak of disease among parrots in The Philadelphia Zoological Garden. Beck and Eber (1929) reported on the loss in ducklings 1 to 14 days old due to B. gallinarum infection. Truche (1923) found that pheasants, swans, grouse, sparrows, ring doves, and ostriches commonly became infected, but that the duck, goose, and turkey were more resistant. Johnson and Anderson (1933) reported outbreaks of the disease in ducklings, turkeys, and guinea fowl. The infection has been observed in wild birds, in quail, grouse, and pheasants. These birds are susceptible by feeding or injection of cultures. Te Hennepe (1939) states that fowl typhoid has decreased in the Netherlands during the past ten years from a point at which it caused some 8.0 per cent of the total deaths in adult birds to 0.7 per cent in 1939. This is considered to be due to greater interest in poultry diseases and improved care of poultry. The disease was at one time one of the most important in Kansas. About 1935 it practically disappeared and is still quite uncommon. The reason for this is not known. El-Dine (1939), in Egypt, states that fowl typhoid is often mistaken for fowl cholera. He reports the disease mainly in chickens and

turkeys, and states that it has been reported in peacocks but has never been seen in pigeons, geese, or ducks. A vaccine was used to confer immunity.

The reports on the susceptibility of pigeons have been variable. Klein reported no success following subcutaneous injection of cultures. Lucet (1891) was unable to infect pigeons with 1.0 cc. doses subcutaneously, while Moore (1895) killed pigeons within 8 days with 2.0 cc. of a broth culture. Pfeiler and Roepke (1917) killed pigeons by injecting 1.0 cc. of a 24-hour broth culture, but the heart blood of these birds would not cause infection in a second pigeon. Kaupp and Dearstyne (1924) caused the pigeon to become sick on the third or fourth day with recovery on the fifteenth day. Kraus (1918) produced death in a pigeon within 4 days by use of 1.0 cc. of a 24-hour broth culture of the fowl typhoid organism. Te Hennepe and van Straaten (1921) claim that pigeons are not always susceptible to inoculation with these organisms. At the Animal Disease Station in 1946, four pigeons were killed in an average period of 4.5 days by intraperitoneal or intramuscular inoculation with 1.0 ml. of a 5-hour broth culture of S. gallinarum.

Hinshaw (1930) reported that the disease caused greater losses among California turkeys than did blackhead. Hinshaw and Taylor (1933) reported an ovarian infection of a turkey hen from which they isolated the organism. Hudson and Beaudette (1929) state that there is a difference of opinion as to the incidence of fowl typhoid among avian species, but that there is evidence that it is greater than is ordinarily suspected. A lack of accurate field diagnosis undoubtedly results in many discrepancies. Lerche (1939) reports one case of an infection of humans with a culture very similar, but not identical, to S. gallinarum, and the Duisburg strain of S. gallinarum was originally obtained from linarum was originally obtained from acute gastroenteritis in man. Cloud (1943) reported the isolation of the Duisburg strain from a patient with severe

peritonitis. The organism was not found in the stools. However, this organism should not be considered a human pathogen.

It is not difficult to infect rabbits with fowl typhoid bacilli. Pfeiler (1920) succeeded in inducing infection four times in 15 rabbits. Guinea pigs and pigeons are very resistant, although, as has been observed repeatedly, pigeons die if the dosage is somewhat large. Van Straaten, te Hennepe, and Pfeiler were quite successful in infecting white and gray mice, while rats, dogs, and cats were shown to be immune. A relatively small number of avian species appear to be susceptible, although there is a difference of opinion as to the incidence of this disease. Hinshaw and Taylor (1933) inoculated two mature rabbits intravenously with 0.5 and 1.0 cc., respectively, of a 48-hour broth culture; the animals lived. The one receiving 1.0 cc. was killed three weeks later, and the blood was found infectious for young rabbits. Smith and Ten Broeck (1915) stated that the pathogenicity of *S. gallinarum* was relatively feeble for laboratory animals. The rabbit succumbed to relatively large doses (0.3–0.5 cc.) of a 24-hour broth culture given intravenously. Pfeiler and Rehse (1913) state that pigeons, geese, and ducks are resistant to the infection, but mice succumb. Rats, cats, and dogs fail to show any disturbance after eating diseased material.

Smith and Ten Broeck found a toxin in the filtrates of broth cultures of *S. gallinarum*. It appeared in the culture at the end of 2 days at 37° C. and caused prompt death of a rabbit by the intravenous route. Death resulted within 2 hours and in many respects was like an anaphylactic shock. It is probably an endotoxin which is stable at 60° C. for 1 hour. Boiling for 15 minutes reduces its activity.

Rao et al. (1952) reported *Salmonella gallinarum* to be equally pathogenic to baby chicks and adults under natural conditions.

They all reported their organism to be fatal to pigeons, guinea pigs, and rabbits.

Smith (1955b) reported that immunity appeared to be solid when massive doses of *Salmonella gallinarum* were administered either orally or intravenously to clinically recovered chickens.

One-day-old chickens were most susceptible. This was followed by a decrease in susceptibility until maturity when it again increased. There was no difference in susceptibility due to sex.

Van Es and Olney (1940) exposed fowls to artificial infection and observed that the losses were variable and that the birds which contracted the disease showed a considerable degree of variation in the length of their survival. This difference was probably due to individual variation in susceptibility.

Symptoms. The incubation period, as a rule, is from 4 to 5 days, although this varies considerably with the virulence of the organism, and the course of the disease is about 5 days.

Comb and wattles are generally pale and shrunken, especially in the subacute cases. In acute cases, however, the comb and wattles may be dark colored, as in fowl cholera. The birds become listless and inactive and prefer to separate from the flock. A thin greenish-yellow diarrhea appears early; there is complete loss of appetite; intense thirst as in fowl cholera is common, presumably as the result of high fever. Investigations at the Kansas Station would indicate that there is no difference in the temperature range of fowl cholera and fowl typhoid; temperatures of 110° to 112° F. are common. Respiration is at first accelerated. In some cases death occurs suddenly at the end of the second day. Comb and wattles appear anemic instead of cyanotic as in fowl cholera. The anemic condition becomes pronounced in prolonged cases. Mortality is variable. In acute outbreaks losses may be heavy in the beginning, followed by a tapering off to an occasional death in the chronic stage. Fowls visibly sick generally do not survive.

Pathology. In peracute cases little or no gross tissue changes are observed. In the more prolonged cases, however, marked

FIG. 10.1 — Subacute fowl typhoid. Grayish-white foci in myocardium and swollen "bronze" liver.

changes begin to appear, the most common of which are swelling and redness of the liver, spleen, and kidneys. These lesions are frequently seen in young birds. In the subacute and chronic stages of the disease the greenish-brown or bronze and swollen livers are commonly seen. Other changes include grayish-white foci of the miliary type in the liver and myocardium, pericarditis, peritonitis due to ruptured ova, hemorrhagic, misshapen and discolored ova, and catarrhal inflammation of the intestines. In young chicks grayish-white foci may sometimes be observed in the lungs, heart, and gizzard, as in pullorum disease (Fig. 10.1).

In acute cases the blood picture is changed very little. If the disease lasts a few days, however, the changes mentioned in Table 10.3 are observed.

Beck and Eber (1929) recognized great loss from *B. gallinarum* infection among ducklings 1 to 14 days old. Maltose, dulcite, and dextrin were fermented with acid formation by the organism isolated. The disease picture was similar to the one observed in pullorum infection in chicks. The ducklings were sick only a short time. The anatomical changes were the following: hemorrhage in the pericardium, slight swelling of the spleen, catarrhal inflammation of the lungs and intestines. Small necrotic foci in the lungs, as frequently observed in chicks with pullorum disease, did not occur. In adult ducks the changes of the ovary and the yolk were frequently the same as those found in adult hens. Fowl typhoid organisms were isolated from the misshapen yolks.

Gauger (1934) obtained the organism of

TABLE 10.3

CHANGES OF THE BLOOD WITH FOWL TYPHOID (WARD AND GALLAGHER, 1920)

Date	Temperature in C.	Number of Red Blood Corpuscles Per cm.	Number of White Blood Corpuscles Per cm.	
March 26 ...	41.5	3,535,000	18,940	Healthy
March 28 ...	43.5	2,430,000	70,000	Chicken eats very little
April 2 ...	43.8	1,684,210	80,000	Blood very pale; chicken weak, refuses food
April 3 ...	41 3	1,745,000	245,000	Very weak, very many red blood corpuscles attacked by leucocytes
April 4 ...	......	......	......	Found dead

fowl typhoid from focal lesions in the testicles of a rooster. The culture was pathogenic for other roosters by inoculation and feeding. Although various foci had been described, this was the first case described for focalization in the testicles.

Beaudette (1938) states that the disease in the guinea is interesting because the affected birds show respiratory symptoms characterized by a severe congestion with collection of mucus in the nasal cleft and trachea. The lungs were congested, and the organism could be isolated from the nasal exudate.

Johnson and Pollard (1940) studied an outbreak of disease which resembled pullorum disease in week-old turkey poults. The necropsy revealed a large retained yolk, and the liver appeared somewhat friable and of creamy-white color. The surface was mottled with slight hemorrhagic areas. A slight congestion of the anterior portion of the duodenum was found. The organism isolated was a Gram-negative rod producing acid but no gas from dextrose, mannite, dulcite, xylose, sorbite, arabinose, maltose, levulose, and dextrin, but did not react with lactose, sucrose, or inositol. Serologically the organisms checked with S. gallinarum. This organism was isolated from the ovaries of the adult birds that supplied the poults. It appeared to be a very chronic disease in these birds. By testing at frequent intervals with a pullorum antigen the percentage of reactors in the flock was reduced from 8.7 to 6.0 per cent. However, it was considered as doubtful if the infection could be completely eliminated in this manner.

Rao et al. (1952) reported the presence of a band of hemorrhage in the submucosa of the proventriculus, and cyanotic instead of anemic comb and wattles in the adult.

Smith (1955b) produced fowl typhoid in chickens by the oral administration of Salmonella gallinarum. Infection took place in the intestinal tract with localization in the intestinal wall, liver, and spleen. This was followed by a bacteremia and death or chronic disease with proliferative lesions in the intestinal and heart walls. Of 300 nine-week-old cockerels, 45 per cent died of the acute disease and 15 per cent died in the chronic stage. S. gallinarum was shed in the feces up to two to three months after infection. This was associated with focal infection in the intestinal wall.

Diagnosis. In general it is not difficult to diagnose fowl typhoid clinically. The disease is not as acute as fowl cholera, monocytosis (pullet disease), or fowl plague. In these latter diseases, as many birds are sometimes lost in a few hours as are lost with fowl typhoid in as many days. On necropsy the differences exhibited by these diseases are generally quite evident. The marked swelling of the liver in fowl typhoid is not found in fowl cholera and fowl plague, and the general hemorrhagic character of the last two diseases is more

TABLE 10.4
FERMENTATION REACTIONS OF COMMON POULTRY PATHOGENS

	Dextrose	Lactose	Maltose	Sucrose	H₂S	Indol
S. gallinarum	AG	—	?	—	?	—
S. pullorum	AG	—	— *	—	+	—
S. anatis	AG	—	AG	—	+	—
S. typhi-murium	AG	—	AG	—	+	+
P. avicida	A	—	—	A	—	+
E. coli	AG	AG	AG	?	?	+
Staphylococci	A	A	A	A	—	—

AG = acid and gas; A = acid; — = no change; ? = slight; + = positive.
* Of the large number of cultures of S. pullorum which were isolated in the Laboratory of Bacteriology, Manhattan, Kansas, the maltose-fermenting type was very rare.

common. Petechiae are observed in fowl cholera or fowl plague more frequently than in fowl typhoid. The bronze-colored liver makes almost certain the diagnosis of fowl typhoid. Also, the microscopic blood picture differs in fowl typhoid from that in fowl cholera and fowl plague. A few rods resembling colon organisms may be seen in the preparations from cases of fowl typhoid; in fowl cholera the bipolar organisms are very common; in plague no bacilli are found in the blood. As a means of differential diagnosis a chicken and a rabbit may be inoculated with some material from the diseased bird. In fowl cholera both animals die in 1 or 2 days; in plague, only the chicken dies in 2 to 4 days; in fowl typhoid, the rabbit generally survives, the chicken remains alive or dies after 6 to 10 days.

A laboratory diagnosis is quite easy. The organism grows readily on ordinary laboratory media and may be identified by bacteriological or serological methods. Table 10.4 will be of value in this diagnosis.

The S. anatis may be separated from S. typhi-murium by fermentation of inosinol. S. anatis fails to ferment it while the latter ferments it with production of acid and gas.

A positive antipullorum serum will be of value in making a slide agglutination test. This, however, will not differentiate the two organisms, but is a valuable adjunct to the fermentation reactions.

Mallmann et al. (1928) reported on the use of brilliant green in the isolation of S. gallinarum. The growth of the organism was not affected by freshly prepared solutions of 1 to 75,000, while the dye exerted an inhibitory effect on E. coli, as previously described by others. The bacteriostatic effects of different lots of dye from different manufacturers were found to be decidedly different. These results were confirmed by Kerr (1950). Delpy and Rastegar (1938) found that this dye could be used to advantage for the isolation of the pullorum-gallinarum group and its intermediates.

Fowl typhoid in chickens may be confused with fowl cholera and monocytosis in the field. This is especially true if the diseases are acute. If the birds die quickly with fowl typhoid, the liver is lighter than normal, with pale streaks. In monocytosis the most characteristic change of the liver consists of round, yellowish areas with hemorrhagic centers. No degeneration of the skeletal muscle is observed in fowl typhoid, while it is fairly diagnostic for monocytosis.

It should be emphasized that the final differential diagnosis must be made in the laboratory where the organism can be isolated and identified. (No organism can be isolated which will cause monocytosis.)

At the twenty-second annual meeting of the Northeast Conference of Laboratory Workers in Pullorum Disease Control (1950), the committee on standardization

of cultural examination of reactors for fowl typhoid recommended the use of an enrichment medium such as selenite. Into 20 cc. of this enrichment broth a one gram portion of the organ to be cultured is dropped. After 24 hours incubation the culture is plated on SS agar and bismuth sulfite agar. The use of tetrathionate broth, with brilliant green as an enrichment medium and MacConkey's agar, desoxycholate, and D.C.L.S. as a selective medium, is optional. Identification is made by the use of dextrose, lactose, sucrose, and maltose, the first and last of which are fermented. Reactors are further identified by the indol test and urease activity.

The agglutination test, using antigen made from S. gallinarum or S. pullorum, can be used to detect the birds infected with S. gallinarum.

METHODS OF CONTROL

In the control of infectious diseases of poultry, several procedures are available, including prevention (immunization, sanitation, and breeding for resistance), treatment, and eradication (elimination of carriers and depopulation). The procedure to employ depends on the type of disease being dealt with and the type of poultry industry in which it is found. Most well-established virus diseases are best controlled through vaccination. On the other hand, most bacterial diseases respond poorly to vaccination, but some of them can be controlled by detection and elimination of carriers. The latter procedure is highly recommended for the control of fowl typhoid.

Van Roekel (1962) discusses additional measures required for the eradication of pullorum-typhoid infections, and cites the following procedures which were adopted and recommended in 1960 by the American Association of Avian Pathologists as a guide for a basic eradication program:

1. The basic principles for identification of a U.S. pullorum-typhoid-clean flock under the National Plans are acceptable as the starting point for an eradication program.

2. A federal regulation should be adopted to control the interstate movement of poultry from the standpoint of pullorum disease and fowl typhoid. If this does not receive adequate support, then each state should develop its own state regulation controlling the importation of hatching eggs and poultry from the standpoint of pullorum disease and fowl typhoid.

3. All turkey and chicken breeding flocks as well as other fowl in the state should be under a pullorum-typhoid control program and should be classified as U.S. pullorum-typhoid-clean or the equivalent.

4. All outbreaks of pullorum disease and fowl typhoid should be reported to the proper state agency with regulatory power, such flocks should be quarantined, and the marketing of such flocks should be in a plant under state or federal supervision. Other types of Salmonella and Arizona infections should be reported to the proper state agency.

5. Poultry consigned to public exhibitions such as county and state fairs and poultry shows should originate from U.S. pullorum-typhoid-clean flocks or the equivalent.

6. A state or area may be designated as pullorum-typhoid-free if all turkey and chicken breeding flocks are classified as U.S. pullorum-typhoid-clean or the equivalent and no flocks are under quarantine in the area.

Wilson (1958) reports an increased incidence and wider distribution of fowl typhoid in recent years. Control measures consist of prompt diagnosis, immediate therapeutic treatment with furazolidone 0.04 per cent for 10–12 days, and removal to fresh quarters preferably followed by another course of treatment and the use of the agglutination test to detect carriers. An effective preventive vaccine is not at present available, but one now under test has shown promise.

Machan (1959) from twenty years' ex-

perience with slow serum and rapid whole-blood agglutination tests for pullorum disease stated that the disease cannot be efficiently eradicated from an infected flock by systematic blood testing at 6-week intervals unless the houses and yards are thoroughly disinfected. In Austria, delivery of hatching eggs, permitted according to official regulations, for 9 months from the time of blood examination, has proved too long a time in practice. The reduction of this period to 6 to 8 weeks is recommended by the appropriate ministry for infected flocks.

Winmill (1961) recommends the following procedure for the control of fowl typhoid: (a) destruction of all sick birds; (b) complete destocking of all infected pens; (c) vaccination with 1909S of all birds separated from the focus of infection and negative to the agglutination test; (d) repeated vaccination of young birds (at 8 and 16 weeks of age).

Breeders who vaccinate laying fowls with 1909S are advised to avoid the incubation of eggs for six weeks after vaccination.

The control of *Salmonella pullorum* infection (pullorum disease) by agglutination testing and removal of reactors was begun on a nationwide scale in 1936 through the adoption by the poultry industry on a voluntary basis of the National Poultry Improvement Plan (now the National Poultry and Turkey Improvement Plans) suggested by the Poultry Research Branch, Animal Husbandry Division, Agricultural Research Service, U.S. Department of Agriculture, but it was not until 1951 that the closely related *Salmonella gallinarum* infection (fowl typhoid) was included in the Plans. The disease control section of the national Plans through its agglutination testing and removal of reactors has been very successful in reducing pullorum disease to a small fraction of 1 per cent of the birds tested. It is hoped this testing program will reduce the incidence of fowl typhoid as well, and that it will also prevent the vastly

destructive fowl typhoid epizootics such as that which swept the eastern seaboard in the 1940's including "pullorum-clean" flocks.

Prevention

1. Immunization. Attempts have been made to immunize fowl with killed fowl typhoid cultures. According to some writers the results of this type of treatment are of little value. However, it cannot be denied that killed bacteria of the group possess some antigenic properties. McNutt (1926) experimented with various commercial vaccines on about 725 chickens and concluded that they have no value for the control of fowl typhoid. It is probable that repeated vaccination will produce a better degree of immunity than one treatment. Experiences from field practice point in that direction. Bushnell and Patton (1924) found that three vaccinations at about 5-day intervals reduced the mortality from some 30 to 5.6 per cent in birds occupying contaminated runs. The results of vaccination are difficult to evaluate because of the natural variation in normal resistance.

Panisset (1950) states that vaccination against fowl typhoid, in spite of its imperfections and its failures, even when carried out with stock vaccines is in the majority of cases an effective weapon in the struggle against the disease. Strict attention must be paid to the observation of hygienic measures. Referring to the control of both fowl typhoid and pullorum diseases, Manninger (1950) states in part that no results whatever toward the control of the disease can be obtained by the use of biological products. However, an efficient method of control consists in careful elimination and killing of the reactors. The agglutination test renders quite satisfactory results, and a prompt and reliable eradication of the disease from a flock depends largely on repeated blood testing. Dearstyne *et al.* (1933) recommended that control practices revolve around a rigid quarantine of the flock; destruction

of all birds showing symptoms of the disease; disinfection of houses, utensils, and drinking water; and the vaccination of all well birds.

Coles (1946) recommends for prevention two vaccinations a week apart, each consisting of a 1 cc. subcutaneous injection. Immunity takes 12 to 14 days to develop and lasts about 9 months. He states that successful eradication of fowl typhoid depends on a combination of:

1. Hygiene, i.e., clean houses, uncontaminated food and water, and proper disposal of feces.
2. Vaccination — failures of vaccination are said to be due to neglect of the necessary hygienic measures.

Wilson (1946) found killed culture vaccines ineffective in protecting against artificial exposure to S. gallinarum. This was true of both autogenous and stock vaccines. However, when a dose of autogenous vaccine was followed by a dose of live culture, a solid and lasting immunity was produced, but this procedure was not recommended.

Hall et al. (1949b) reported experiments on the use of bacterial vaccines in fowl typhoid. Vaccines were prepared by killing cultures of S. gallinarum with formalin, phenol, chloroform, brilliant green, and crystal violet. All except the crystal violet vaccines were suspended in beeswax and peanut oil. Injections were made subcutaneously, intraperitoneally, intramuscularly, and into the crop. No significant protection was observed after the vaccinated birds had been exposed to infection two to four weeks later.

Smith (1956) reports that a good immunity was produced in chickens against oral infection with Salmonella gallinarum by the use of either a smooth (9S) or rough (9R) attenuated vaccine. Killed vaccines had no effect. The immunity produced by the rough strain was limited to about 12 weeks, while that produced by the smooth strain was complete to at least 34 weeks.

The rough strain vaccine, 9R, did not produce agglutinins against smooth S. gallinarum in chickens. It was not lethal to one-day-old chicks, and did not cause a fall in egg production in laying hens. On the other hand, the smooth strain, 9S, produced agglutinins, killed one-day-old chicks, and was accompanied by a marked drop in egg production.

Gordon et al. (1959) submit evidence confirming the efficiency of attenuated live vaccines of Salmonella gallinarum 9S and 9R in conferring immunity against fowl typhoid.

There was no difference in susceptibility to, nor in response to, either vaccine among the four breeds tested.

Vaccination at 8 weeks of age produces an appreciably better immunity than at 4 weeks of age.

The use of vaccine 9R in the field appears justified in that it confers an appreciable degree of immunity without seriously interfering with the routine blood test for carriers of Salmonella pullorum and, in addition to possessing a low level of virulence for chicks, its transmission through the egg from vaccinated laying birds appears to be almost negligible.

The avirulent smooth strain 9S provided the better immunity but has the disadvantage of interfering with the blood test.

Gordon and Luke (1959) confirmed the value of the 9R vaccine in the control of fowl typhoid in Northern Ireland. In two breeding flocks blood agglutinins developed to the extent of 6.12 per cent and 5.83 per cent respectively.

The vaccinal strain was isolated 11 months after vaccination and there was presumptive evidence that vaccination of adult birds with the rough strain may induce pathological changes in the ovary in some birds.

Harbourne (1957) conducted field trials to assess the value of two live attenuated vaccines, one a rough strain of Salmonella gallinarum (9R) and one a smooth strain (9S) as a means of preventing and controlling fowl typhoid.

Preventive vaccinations were performed

at 43 farms; one-third of the birds of each flock received one ml. of vaccine 9R subcutaneously, one-third 0.2 ml. of vaccine 9S subcutaneously, and the remaining one-third was left unvaccinated.

In 18 flocks where losses from fowl typhoid were slight, 0.9 per cent of the deaths occurred in birds vaccinated with 9R, 0.4 per cent in birds vaccinated with 9S, and 2.4 per cent in unvaccinated controls.

At seven of the farms where losses from fowl typhoid were appreciable, after the first 14 days from the start of the trial 1 per cent of the birds vaccinated with 9R, 1.7 per cent vaccinated with 9S, and 11 per cent of the unvaccinated birds died from fowl typhoid.

At two of the farms the survivors were killed without blood testing. A smooth strain of *S. gallinarum* was recovered from a high proportion of the birds in each of the 3 groups.

In five flocks where fowl typhoid had previously been diagnosed, two-thirds of the birds of each flock received one ml. of 9R vaccine subcutaneously; the remaining third was left unvaccinated. Significant losses from fowl typhoid occurred at two farms. At one of these farms vaccination apparently precipitated death. At the other, 5 per cent of the vaccinated birds and 39 per cent of the unvaccinated birds died from fowl typhoid.

It is suggested that treatment with furazolidone followed by vaccination might be a useful procedure in flocks where an early diagnosis of fowl typhoid is made.

2. Sanitation. In the prevention of the spread of infectious diseases, sanitation appears to play an important role. Van Es and Olney (1940) subjected two groups of birds to opposite extremes in sanitation, and noted the effect on losses from fowl typhoid. In the sanitary yard the ground was covered with gravel and the house had wire floors. The water fountains were self-cleaning, and the feeders were covered to prevent contamination as much as possible. In the other pen the yard was dirt and ungraded, and the birds ate and drank from open vessels. A total of 80 fowls succumbed to fowl typhoid from the two pens when infected fowls were introduced. In the sanitary pen 10 died from fowl typhoid, and 70 died in the unsanitary pen.

On the other hand, Hall *et al.* (1949a) found that an unsanitary pen (one highly contaminated with the discharges of fowls sick with acute fowl typhoid) produced only 20 per cent as much fowl typhoid in susceptible fowls as the same pen occupied by sick birds when the susceptible birds were put in. In other words, these experiments indicate: (1) that the sick bird is probably the worst spreader of the disease and should be removed promptly, and (2) that the fowl typhoid organism, *Salmonella gallinarum*, rapidly loses virulence after discharge from the bird's body, and consequently, a short period of vacancy before restocking greatly reduces the probability of an outbreak.

After an outbreak the following sanitary measures may be helpful: Very sick birds should be killed and burned or buried deeply. The building must be thoroughly cleaned; walls, perches, nests, and apparatus should be scrubbed with lye water (1.0 pound of lye dissolved in 15 gallons of hot water). The upper surface of earth floors should be replaced with fresh soil; cement floors should be cleaned and disinfected. The dropping boards should be cleaned. Feeding pans and drinking vessels as well as all other utensils should be thoroughly scoured with lye water and rinsed. Sometimes a hot solution is preferable because of the resistance of protozoan parasites to the action of chemical disinfectants. This is especially true in case of coccidia and worm eggs. After the building has been cleaned, dried, and aired, the walls may be whitewashed. An antiseptic whitewash may be prepared by adding 5.0 per cent crude carbolic acid. Yards and runs should be arranged so that all parts are exposed to direct sunlight at some time during the day.

Puddles and pools must be eliminated. Pigeons, mice, and rats are to be kept away from the premises. If there are several chicken houses to be served by the same attendant, a mat dipped in disinfectant may be placed so that shoes are cleaned before entering each house.

Botts *et al.* (1952), investigating the bactericidal effect of old built-up litter compared with new cob litter, found that when six-week-old chicks were placed on the litters 48 hours after they were sprayed with *S. gallinarum*, the mortality was lower on old built-up litter than on new cob litter.

3. Increasing resistance by breeding and by diet. Breeding and selection for resistant strains of birds may be an important means of control. Lambert (1933) showed that selection for resistance to fowl typhoid in chickens resulted in a decided decrease in the mortality of selected stocks. Since *S. gallinarum* and *S. pullorum* are closely related organisms, it was decided to test fowl typhoid resistant stock for susceptibility to *S. pullorum* infection, and an *S. pullorum* stock for susceptibility to *S. gallinarum*. Results indicated that selection for resistance to one pathogen affords some protection to infection with one closely related. It was suggested that the resistance was to some extent due to nonspecific factors.

Garren and Hill (1959) made agglutinating antibody determinations for White Leghorns, Rhode Island Reds, and White Leghorn-Rhode Island Red crosses after inoculation with live and killed *Salmonella gallinarum* cultures (fowl typhoid). White Leghorns consistently developed lower antibody titers than Rhode Island Reds whether induced by infection or by bacterin. Leghorn-Red crosses were intermediate between the two breeds in antibody titers but possessed almost the same marked resistance to fowl typhoid as observed for the Leghorn.

Smith (1954) found that different infection rates were observed when different foods containing similar numbers of *Salmonella gallinarum* were fed to chickens.

The main reason for this was that certain properties of some of the foods had a profound influence on the bactericidal action of the gastric juice in the gizzard. One of these properties was physical consistency, and another was the ability to maintain a relatively high pH in the gizzard. A diet of whole wheat only was especially effective in lowering the pH of the gastric juice with consequent destruction of *S. gallinarum* and a decrease in the infection rate. It is suggested that when a natural outbreak is diagnosed in a flock it would be worthwhile to alter the diet to whole wheat only until it is possible to institute other methods of control.

Hill and Garren (1955) demonstrated that high levels of all known required vitamins increase the resistance of chicks to fowl typhoid. The enhanced resistance observed when high levels of vitamins are fed is apparently not due to a uniform increase in requirements for all vitamins. Some vitamins must be increased over the requirement for growth many times more than others in order to bring about increased resistance to typhoid. In addition to the essential vitamins at high levels, an antioxidant is required in the diet in order to increase resistance of the chick to fowl typhoid. It was also found that it is possible to oversupplement the diet with vitamins insofar as obtaining maximum resistance to oral inoculation of the *Salmonella* organism. The exact mechanism of all the phenomena observed in these studies is not known.

Hill and Garren (1958) showed that the plasma ascorbic acid levels of chicks with fowl typhoid were reduced. Supplementation of the diet with 0.1 per cent ascorbic acid resulted in an increased plasma ascorbic acid level at all times throughout the experimental period.

From the sixth to the ninth day, the period of heaviest mortality, the plasma ascorbic acid level of the basal-fed group was unchanged, while that of the supplemented group increased significantly. During this time, 20 per cent of the basal-

fed group died, while only 11.2 per cent of the supplemented group died. This difference was statistically significant ($X^2 = 4.620$, P .05).

Chubb et al. (1958) testing the effect of feeding high levels of vitamins on the susceptibility of 3 breeds of chickens to experimental Salmonella gallinarum infection found that the administration of high levels of all the required vitamins in the diet for four weeks prior to infection or at infection had no effect on the average survival time or total mortality in 8-week-old Rhode Island Red or Brown Leghorn chickens. Neither did separation of these vitamins into the fat-soluble or water-soluble groups and their administration in the diet of high levels for four weeks prior to infection have any effect on the average survival time or total mortality in these two breeds of chickens.

With White Leghorn chickens infected with Salmonella gallinarum a great variation in response to the high level feeding of vitamins was encountered. Some results would suggest that the feeding of high levels of vitamins for four weeks prior to infection may increase the susceptibility of this breed to Salmonella gallinarum and this may possibly be associated with the fat-soluble group (A, D, E, and K).

Smith and Chubb (1957) found that the protein level of the diet affected the mortality rate of chickens infected with Salmonella gallinarum. A simple diet of ground wheat plus 2½ per cent fish meal gave the highest resistance to S. gallinarum infection. A much higher or lower level of fish meal had an adverse effect on resistance to infection.

Starvation for 48 hours increased the severity of the disease.

Hill and Garren (1961) found that increasing the protein level of diets from 10 per cent to 20 to 30 per cent resulted in a progressively increased rate of mortality of chicks from Salmonella gallinarum infection. The rate of mortality was not affected by the energy content of the diet. The acceleration of mortality was evident whether the protein was supplied by soybean meal or casein. Since the acceleration was noted when the organism was given either orally or intramuscularly, it was concluded that the effect of the increased protein level did not depend on a meeting of pathogen and diet in the intestinal tract. While total mortality was generally increased with increasing protein levels, the differences were not statistically significant in most of the comparisons.

Treatment

Sulfonamide drugs have been tried by numerous investigators with conflicting results. Hammond (1945) reported effective control by use of sulfathiazole. Holtman and Fisher (1946) studied an outbreak in battery-raised chickens which had caused 20 per cent loss in 3 days. The flock was then divided into two parts. Group 1 received the usual care — removal of sick birds and cleaning and disinfection of batteries with a cresol solution. Group 2 was given sodium sulfathiazole in the drinking water for one week. At the end of the week 80 per cent of the birds in group 1 had died. Losses in group 2 had been reduced to 4 per cent with no losses during the last 3 days. However, losses in this group reappeared within 5 days but were controlled by the use of the drug.

The next year, Holtman and Fisher (1947) were successful in controlling natural outbreaks of fowl typhoid in broilers by the use of sodium sulfamerazine (0.2 per cent) in the drinking water. There was a loss of 62 per cent in the controls compared to 4 per cent in the treated birds when the drug was administered for 5 consecutive days each month for 2 months.

Simms (1946) reported on the use of sulfamerazine, sulfadiazine, and sodium sulfathiazole in broiler plants. The drugs were fed in 0.5 to 1.0 per cent in wet mash. None of these drugs was satisfactory for controlling a virulent outbreak of the disease. Mortality was greatly reduced while the drugs were being fed, particularly in the case of sulfamerazine, but on discon-

tinuance of its use, mortality rose again to nearly its former level. The same results were obtained from the use of these drugs in breeding flocks.

Moore (1946c) reported that sulfamerazine was effective in reducing death losses from fowl typhoid, while sulfathalidine and sulfasuxidine were not effective. The mortality varied from 33.3 to 83.3 per cent for these two drugs. However, the former was given 5 days after exposure while the latter was started at the time of exposure.

Alberts (1950) used 0.4 per cent sulfamerazine-mash mixture, or 0.2 per cent sodium sulfamerazine in the drinking water during a 7-day course of treatment. This prevented losses during the 7-day period of treatment and for 2 days after. The intermittent use of sulfamerazine or sodium sulfamerazine over a 21-day period was more effective in minimizing losses than was continuous feeding of the drug for 7 days.

Jones et al. (1944) reported on the use of streptomycin to protect chicken embryos from the action of the fowl typhoid organism.

After completing two large experiments on the effect of treating turkeys suffering from fowl typhoid with furazolidone (NF-180), Boney (1954) reported this drug to be effective in reducing mortality due to fowl typhoid when fed at the rate of 2 pounds per ton of feed for 7 to 10 days, or until mortality stops. He also recommends the use of sanitary procedures after an outbreak.

Grumbles et al. (1954) found furazolidone added to the feed at levels of 0.0055 to 0.011 to be effective in preventing mortality associated with fowl typhoid (S. gallinarum) infection in turkeys. The higher level at 0.011 per cent was found to be more effective in severely infected birds. No evidence of toxicity or unpalatability was encountered. Exposed and treated birds have been shown susceptible to reinfection and to be carriers of S. gallinarum.

Richey (1954) reported that mortality was controlled promptly in field outbreaks of fowl typhoid in one chicken and two turkey flocks after feeding furazolidone (NF-180).

Glantz and Gordeuk (1955) report that in vitro and in vivo tests of sensitivity of Salmonella gallinarum to antibiotics were similar. Chloromycetin, when administered at the rate of 200 mg. per bird per day per os or 1 to 2 gm. per pound of mash, gave excellent protection when started on the day of infection. A relapse occurred when the chloromycetin mash was discontinued. Aureomycin mixed with mash at the rate of 1 gm. per pound reduced losses to 25 per cent and no relapse occurred when treatment was discontinued. Polymyxin B and Terracon 180 had little therapeutic value.

Smith (1955e) found furazolidone to be greatly superior to the sulfonamides in treatment of experimental fowl typhoid in one-day-old and nine-week-old chickens. This was thought to be due to the fact that furazolidone is bactericidal while the sulfonamides are bacteriostatic in low concentration. Penicillin was of no value in treatment.

Fecal excretion of Salmonella gallinarum could be stopped by feeding furazolidone in the mash at a concentration of 0.04 per cent for 10 days.

Chickens treated with furazolidone early but not late in the course of the experimental disease developed little immunity.

Furazolidone was of value in treatment of chronic carriers of infection.

Furazolidone, when fed continuously to young chicks in a low concentration (0.02 to 0.04 per cent), slightly depressed the growth rate but was not toxic.

Wilson (1955) found that furazolidone in a concentration of 0.02 per cent in the mash controlled mortality from Salmonella gallinarum infection but that mortality recurred after treatment ceased. At the 0.04 per cent level complete protection was obtained. When treatment was delayed until deaths occurred, results were less satisfactory but mortality was greatly reduced. Treatment begun at the earliest possible moment with 0.04 per cent of furazolidone and continued for 7 to 10

days, together with the practice of sanitary measures, is recommended.

Wilson (1956) concludes that the administration of furazolidone in the mash in the treatment of carriers will result in a proportion of birds being sterilized of Salmonella and ultimately becoming negative to the agglutination test. A larger percentage continue to harbor the organism, especially in distorted ova, and remain reactors. Treated birds usually cease laying Salmonella-containing eggs. Wilson further predicts that furazolidone may prove even more valuable in the prevention of salmonellosis in turkeys and ducks as direct egg transmission is common in these species.

Titkemeyer and Schmittle (1957) used various levels of six different drugs to determine their effects on the recovery of S. gallinarum from inoculated White Leghorn chicks. Representing the sulfa drugs, sulfaquinoxaline at levels of 0.05 per cent and 0.0175 per cent in the feed or at 0.025 per cent in the water and sulfamethazine at the level of 0.1 per cent in the water resulted in an incidence of recovery of 82.5 per cent as compared to 100 per cent in the inoculated controls. At "growth-promoting" levels, chlortetracycline at levels of 18 gm. and 108 gm. per ton and penicillin at 4 gm. per ton of feed did not result in a significantly lower rate of recovery of the organism. At therapeutic levels, chlortetracycline at 200 gm. per ton of feed resulted in 80 per cent recovery of the organism. With chlortetracycline in water, with neomycin alone or in combination with chlortetracycline in feed, the organism was recovered from 90 per cent of the chicks as compared to 100 per cent of the infected control. Furazolidone at the rate of 100 gm. per ton of feed reduced the incidence of recovery of the organism to only 10 per cent. With oral inoculation of the organism, the results were less conclusive in that often the organism could not be recovered regardless of whether the chick was medicated. Furazolidone seemingly prevented recovery of the organism in all 30 orally inoculated chicks. Time of administration of the medicaments whether 48 hours before, at time of, or 48 hours after, did not alter significantly the recoverability picture.

Dijkstra (1959) states that treatment of fowl typhoid with chemotheraputics and antibiotics nearly always gives unsatisfactory results because clinically healthy animals may remain carriers for a long time. Furazolidone, which has a bactericidal effect and apparently distinguishes itself favorably from the other drugs, cannot as a rule cure an infected flock.

Richey and Morgan (1959) artificially infected turkeys, 10 days old, with approximately 10^6 Salmonella gallinarum cells. While mortality in the untreated control group was 100 per cent, death losses were prevented by feeding chloramphenicol at 0.22 per cent, or furazolidone at 0.011 per cent or 0.022 per cent in feed starting 5 days before inoculation and continuing for 17 days.

When treatment was begun at the time of infection and continued for 12 days, deaths occurred in all groups. When medication was started four days after inoculation and continued for eight days, more birds treated with furazolidone than chloramphenicol survived. Chloramphenicol given at the rate of one 50-mg. capsule daily for three days was of little value in preventing deaths when given either at the time of inoculation or at the appearance of illness four days later.

Agglutination tests were negative in only one of the survivors medicated with chloramphenicol, but were negative in many of the survivors medicated with furazolidone.

Bierer et al. (1961) in four experiments found that prophylactic furaltadone water medication at 0.25 g/gal resulted in a marked reduction in mortality in pullorum disease in chicks, fowl typhoid in chicks and poults, and S. typhi-murium infection in poults.

Therapeutic medication at 0.25 g/ga

resulted in a reduction in mortality in all four trials. However, mortality reduction was marked on the 0.5 g/gal level in 3 of 4 trials but erratic results were obtained in poults with *S. typhi-murium* therapeutic medication.

In general, average body weights of all medicated groups at 10 days compared favorably with uninfected unmedicated controls, but were lower in the infected unmedicated groups.

Further evaluation of furaltadone water medication in more extensive floor pen trials, under field conditions, is indicated.

Hall and Cartrite (1961) investigated the resistance of some strains of *Salmonella gallinarum* to furazolidone and concluded that fowl typhoid is still a problem of major importance in Texas turkeys and chickens. Three of the four Texas Poultry Disease Investigation Laboratories reported one or more outbreaks of fowl typhoid that failed to respond to furazolidone therapy. Four isolates of *S. gallinarum* from such outbreaks were studied in the laboratory. All were sensitive *in vitro* to furazolidone; however, one strain developed resistance when serial passages were made in the presence of the drug. The same strain displayed resistance to the activity of furazolidone in experimentally infected turkeys when the drug was supplied in the feed at a level of 0.011 per cent (2 lb. NF 180 per ton).

Richey (1962) inoculated day-old chicks with *Salmonella pullorum* or *Salmonella gallinarum*. Medication with either of two soluble nitrofurans (nitrofurazone and furaltadone) in drinking water, alone and supplemented with furazolidone-medicated feed, prevented and reduced early (ten day) and total (four week) mortality in all but one group (infected with *S. pullorum* and treated with furaltadone).

Salmonella gallinarum-infected chicks succumbed rapidly. However, medication with furaltadone decreased both the early and total mortalities considerably. Appropriate time of medication rather than drug used accounted for the lowest number of infected survivors yielding a positive agglutination test.

In most cases, average weight of surviving *S. pullorum*-infected birds was higher than that of the birds infected with *S. gallinarum*.

Eradication

1. Elimination of carriers. Moore (1917), testing two flocks of typhoid-infected birds, one artificially and one naturally infected, found that they react intermittently just as they may with pullorum disease. He concluded, therefore, that fowl typhoid carriers may remain unnoticed if only one blood test is relied upon to remove all infected birds in a flock. He found that repeated testing at frequent intervals is necessary if all infected birds are to be detected, and that fowl typhoid reactors may appear perfectly healthy and continue to react month after month. Moore made a polyvalent *S. gallinarum* tube antigen which he considered superior to standard pullorum tube antigen in detecting carriers.

Holtman and Fisher (1917), in discussing the control of fowl typhoid, assert that the practice of a regular program of blood testing is an exceedingly important means of controlling the disease.

Hall *et al.* (1919b) were able to control extensive outbreaks of fowl typhoid in a large broiler and breeding flock establishment by repeated whole blood plate-agglutination tests and removal of reactors until no more were found. At first a gallinarum plate antigen was used, but later they concluded that the standard pullorum stained antigen was slightly superior to the gallinarum antigen in detecting carriers. When fowl typhoid first broke out in this establishment, control of the disease was attempted in house after house by depopulation of the affected and adjacent pens, followed by thorough cleaning and disinfection, but without success. It was possible to carry out only limited sanitary precautions at this plant; nevertheless, eradication of the disease was accomplished by the persistent elimination of car-

the Dry Antigen. The dry antigen is next combined with a slight amount of phenol salt solution (phenol 0.5 per cent, salt 0.85 per cent) and allowed to stand for two hours or longer to soften. Then the large, coarse, suspended particles are changed into a fine homogenous mixture by vigorous agitation for ten minutes with glass beads in a shaking apparatus.

Density of the bacterial test-suspension is determined by comparison with the usual standard density of barium sulfate (3 cc. of 1 per cent barium chloride solution and 97 cc. of 1 per cent sulphuric acid).

The *Salmonella gallinarum* dry antigen has been in use in the Giessener Institute since 1918. Up to the present time over a half million blood tests have been conducted in the vicinity of the poultry health service by the slow (tube) agglutination method. The antigen has proved satisfactory in all cases with regard to reaction capability, uniformity of composition and simplicity of preparation of the test-suspension. Also all comparative tests with the freshly prepared antigen (Taubitz, 1947; Zurich, 1919; and Geisler, 1958) recognize the clear superiority of the dry antigen.

Geissler (1958) states that agglutination antigens, which had been washed out by centrifugation and sedimentation, have a better reaction than "non-washed" bacteria. Dry antigen, following a method indicated by Lerche and Roots (1958) proves the same specificity and sensibility as cleaned, freshly prepared antigens. The dry antigen, which can always be produced in the same quality, seems to be the best reagent.

Molnar and Nagy (1959) describe the production of fowl typhoid antigen by fermentation, viz.: *S. gallinarum* may be readily cultivated by fermentation using a liquid medium containing hydrolyzed casein. As the result of investigations the propagation of bacteria was finished after 7-8 hours' culture and by this time the culture contained 120 to 150 milliards of germs per ml. These cultures proved suitable for the preparation of fowl typhoid antigen. As a result of comparative serological tests, using blood samples from both naturally and artificially infected birds, the value of the antigen prepared by fermentation was similar to that prepared from suspensions of agar cultures.

2. Depopulation. Depopulation is the traditional method of eradicating disease, and may be used in small flocks kept for egg or meat production. When followed by a thorough cleaning and disinfection, or by a sufficient interval of vacancy, such a procedure is successful, provided healthy replacement stock is obtained. This method of disease eradication, however, is too costly in most breeding flocks where much expense and years of effort have been devoted to the development of birds of superior quality. Control by depopulation is an emergency measure and indicates that the disease has been insufficiently studied to provide a satisfactory control method.

Fowl Cholera

Fowl cholera (avian pasteurellosis) is an infectious disease affecting practically all species of fowls. It usually appears as a septicemic disease associated with high morbidity and mortality, but chronic manifestations are also of frequent occurrence.

History. According to Gray (1913), various epizootics among fowls occurred in European countries during the latter half of the eighteenth century, and he credited Chabert with the first study of this disease in France in 1782. Maillet, in 1836, cited by Manninger (1929), was the first to use the designation "fowl cholera" in connection with severe losses. Renault and Delafond presented the first experimental evidence of the transmissibility of fowl cholera about the middle of the nineteenth century, according to Manninger.

Rivolta, in 1877, and Perroncito, in 1878, described the presence of microbes having a rounded form, appearing singly, or two combined, in the blood of affected birds.

Toussaint confirmed these observations in 1879 and demonstrated that the organisms were the cause of the disease; he obtained cultures in neutralized urine (Gray, 1913). Pasteur (1880a) isolated and grew pure cultures of the microorganism in chicken broth. In continuing studies, Pasteur (1880b), using fowl cholera organisms, performed his fundamental experiments in the attenuation of bacteria in culture and their use in inducing immunity.

Salmon (1880, 1881, 1883) appears to have been the first to have investigated fowl cholera in the United States, and Higgins (1898) had an early report of disease in Canada.

Incidence. Fowl cholera occurs sporadically or enzootically in most countries of the world, although it is of more frequent occurrence in temperate and warm regions than in northern countries. At times it causes a heavy mortality; at others the losses are nominal. There is evidence of a decrease in the incidence of fowl cholera

[359]

in several countries since about 1930. Van den Hurk (1950) reported that fowl cholera is uncommon in Holland. Woolbridge (1954) stated that the acute type of the disease is not normally present in Great Britain, and outbreaks are usually traced to importations. In Denmark, the incidence of fowl cholera declined sharply following bans on importation of live poultry (Marthedal and Velling, 1954). Iyer and Hashmi (1945) reported that the disease occurs in India far less frequently than is usually believed, and that widespread epizootics are not a feature of the disease in that country.

In the United States, many of the poultry diagnostic laboratories have noted a reduced incidence of fowl cholera in recent years, finding only a few sporadic outbreaks. The decreased incidence may well be associated with general improvements in poultry management practices. On the other hand, Eveleth et al. (1951) reported that the disease is widespread in North Dakota in both chicken and turkey flocks, occurring during the entire year but especially at times of management changes. They stated that the disease appeared to be on the increase. Dorsey and Harshfield (1959) ranked fowl cholera among the three most important diseases of poultry in South Dakota. The highest incidence occurred in the months from August through December. Bierer (1962) reported that pasteurellosis in chickens in South Carolina and adjoining areas exists mainly as a persistent subacute and chronic disease that clinically resembles avian monocytosis and that acute fowl cholera is rarely observed. Hagan and Bruner (1961) reported heavy losses of ducklings on the duck "ranches" of Long Island where the birds are raised in large numbers in very crowded insanitary quarters.

Etiology. *Pasteurella multocida* (*P. avicida*, *P. aviseptica*, *P. choleraegallinarum*, etc.), the causative agent of fowl cholera, is a small nonmotile, Gram-negative, ovoid or elongated rod (Fig. 11.1). It measures 0.25–0.4μ by 0.6–2.5μ but tends towards

pleomorphicity after repeated culture on agar, or prolonged cultivation in broth or carbohydrate media. A capsular substance of a mucoid nature may be demonstrated in recently isolated cultures. In tissues, blood, and recently isolated cultures on blood agar the organism is distinctly bipolar when carefully stained with methylene blue, Giemsa, or carbol-fuchsin. This characteristic is lost with continued cultivation on artificial media.

On beef infusion media the colonies of *P. multocida* are round, flat, and translucent. Fluorescence is noted in colonies of many recently isolated strains. In broth the organism produces a diffuse clouding. A sticky sediment collects in the bottom of old broth cultures. With some strains a flocculent precipitate may be noted which is characteristic of a rough phase of the organism. The addition of sterile serum and use of digested protein or proteose peptone stimulates growth in solid and liquid media.

P. multocida is an aerobe or facultative anaerobe with an optimum growth temperature of 37° C. The optimum pH for growth is 7.2 to 7.4 with a range of 6 to 8.5. It produces indol, catalase, and ammonia. It reduces nitrates to nitrites, reduces methylene blue, does not produce methyl acetyl carbonol, and is negative to
FIG. 11.1 – *Pasteurella multocida*, blood smear, fowl cholera. ×2,000. (From Nowak, *Documenta Microbiologica*, Gustav Fischer.)

the methyl red test. It is not bile-soluble, does not liquefy gelatin or change litmus milk (Merchant and Packer, 1961).

Rosenbusch and Merchant (1939) classified *P. multocida* strains into three groups on the basis of their fermentation of xylose, arabinose, and dulcitol. Group I fermented arabinose and dulcitol but not xylose; Group II fermented xylose but not arabinose and dulcitol. A third group was variable but more nearly like Group I. Dextrose, mannose, galactose, saccharose, and mannitol were fermented by both main groups, but not lactose, maltose, raffinose, trehalose, rhamnose, inositol, adonitol, inulin, salicin, dextrin, and starch. Dorsey (1963a) made a similar study of 409 *P. multocida* strains, all of fowl origin. Three hundred thirty-three (81.42 per cent) were Group I and 69 (16.87 per cent) were Group II. Seven strains (1.71 per cent) which fermented xylose, arabinose, and dulcitol were classified as Group III. Twenty-three additional strains varied from the reactions typical of the three groups. Usually there was correlation between the biochemical group and the agglutinative and immunizing actions of the strains but exceptions were encountered (Dorsey, 1963b).

Roberts (1947) arrived at another classification, recognizing 4 types of *P. multocida* based on immunological differences in cross-protection experiments with mice. Little and Lyon (1943) studied 30 strains of *P. multocida* serologically, dividing them into 3 types. Carter (1955) examined numerous strains by means of hemagglutination tests and proposed 4 types which were designated A, B, C, and D. The following table relates Carter's classification with the earlier designations:

Carter	Types	A	B	C	D
Rosenbusch and Merchant	Groups	I	II		
Little and Lyon	Types	1	2	3	
Roberts	Types	II	I	III	IV

Namioka and Murata (1961a) employed a slide agglutination test in comparison with hemagglutination in capsule typing and found the former satisfactory for cultures with fluorescent characteristics. In continuing studies (Namioka and Murata, 1961b, c; Namioka and Bruner, 1963) attention was given, also, to the somatic (O) antigen of *P. multocida*. Ten O groups were demonstrated within 156 cultures. By correlation of these O groups with the capsule types, 12 serotypes were delineated. Almost all of serotype 5:A cultures were recovered from fowl cholera. Both 5:A and 9:A serotypes were isolated from fowl cholera in turkeys. A few cultures from fowls were O group 2 or 4 and two were of unidentified O group. Two strains of *P. multocida* used by Heddleston (1962) to produce bivalent fowl cholera bacterin were identified as serotypes 5:A and 8:A. Serotypes 5:A, 8:A and 9:A proved pathogenic while other serotypes belonging to capsule groups A, B, and D had little pathogenicity for 3 month-old chickens.

Hughes (1930), studied the colony morphology of 210 freshly isolated strains of *P. multocida*, distinguishing 3 variations. One type, "fluorescent," was associated with outbreaks of acute fowl cholera and was highly virulent. The second type, "blue," occurring in flocks in which cholera was endemic, was of low virulence. A third type, "intermediate," was associated with more severe cholera and was intermediate in behavior.

Carter (1955) described three principal colonial variants of *P. multocida* as follows: (1) mucoid (M) with large flowing colonies on agar, a mucoid deposit in broth, and with moderate mouse virulence; (2) smooth (fluorescent) (F) with medium-sized discrete colonies, diffuse growth in broth, and with high mouse virulence; (3) rough (blue) (I) with small, discrete colonies, showing autoagglutination in broth, and having low virulence for mice. Many of the cultures recovered from carrier fowls and animals, and from chronic processes, were composed of predominantly M variants, and were not typable by agglutination, precipitation, or capsular

TABLE 11.1
Classification of Colonial Variants of *P. multocida*

| Older Designations | Proposed Designations | | Capsule | Reaction in Acriflavine |
	Colonial	Antigenic		
Mucoid........ ..	mucoid	M	+ +	slimy precipitate
Fluorescent... ..	smooth	S	+	cells remain in suspension
Intermediate.... ..	smooth	S	+	partial flocculation
Granular Blue	smooth	SR		flocculation
Rough.... .	rough	R		flocculation

swelling techniques. In a later report, Carter (1957) gave further attention to colonial variation and antigenic characteristics of *P. multocida*. Colony morphology was studied by obliquely transmitted light, and antigenic characteristics by behavior with 1:1000 acriflavine solution. His proposed designations were related to older designations as shown in Table 11.1.

Hall *et al.* (1955) described a microorganism isolated from chickens with chronic fowl cholera and chickens with upper respiratory infection, which differed from other members of the Pasteurella group. It produced acid in maltose, trehalose, and mannose, was nonhemolytic, and did not produce indol. The name *Pasteurella gallinarum* was proposed for this new species. Gibbs (1910) had earlier isolated from ducks an organism resembling *P. multocida* which was maltose-positive and indol-negative. Hemolytic Pasteurellae have been isolated from various types of lesions in chickens and turkeys by Greenham and Hill (1962), Harbourne (1962), and Harry (1962).

Tenacity. *Pasteurella multocida* is readily destroyed by 3 per cent cresol, 1 per cent phenol, and 1:5000 bichloride of mercury. At 60° C., the organism is destroyed in 10 minutes. It remains viable in manure for at least a month (Gartner, 1898) and about 3 months in the decaying carcass and in garden soil (Kitt, 1888). The organism survived in dried blood smears on glass for 8 days at room temperature (Skidmore, 1932).

Van Es and Olney (1940), in studies of the influence of environment on the incidence of fowl cholera, found that the infection hazard had apparently disappeared from a poultry yard two weeks after the occurrence of the last death and the removal of birds.

The influence of temperature on the viability and virulence of *P. multocida* in cultures has been studied by Nobrega and Bueno (1950). Broth cultures stored in sealed tubes at an average room temperature of 17.6° C. were still viable and virulent after two years. At temperatures of 2 to 4° C. such cultures were inactive at the end of one year. Sealed agar slant cultures were held at room temperature for 3 years or longer with only a few strains becoming nonviable (Dorsey and Harshfield, 1959).

Susceptibility. Domestic fowls of all species, game birds raised in captivity, and small feral birds (pigeons, sparrows, finches, etc.) that may visit poultry yards are susceptible to fowl cholera. Most of the reported outbreaks of fowl cholera have involved chickens, turkeys, and ducks, and studies of the disease have more often concerned those species. Curtice (1902) described a heavy loss in 1900 in Rhode Island due to "goose septicemia." About 3,200 geese died out of a flock of 4,000 in a short period of time. Others (Moore, 1916; Ward and Gallagher, 1920) used

the name "goose septicemia" for Pasteurella infections in geese, although the separate identity was apparently based on its peracute nature and the very high mortality in that species rather than on differences in the causative organism. Mohan and Bhadury (1947) provided a later report of fowl cholera in geese. Van Es and Olney (1940) recognized the marked susceptibility of geese to fowl cholera in using that species to test the infectivity of lots after removal of infected chicken populations.

Birds of prey, waterfowl, and other birds kept in zoological gardens occasionally succumb to infection. Mortalities from fowl cholera in wild geese (Zuydam, 1952), wild ducks (Van den Hurk, 1946; Quortrup et al., 1946), and sea gulls (Kaschula and Truter, 1951) have been reported with spread to domestic fowls. A severe outbreak of fowl cholera in the San Francisco Bay area in 1948 was responsible for a loss of an estimated 40,000 waterfowl (Rosen and Bischoff, 1949).

The disease has been reported in pheasants raised in captivity (Hudson, 1944; Alberts and Graham, 1951), and in captive quail (Hinshaw and Emlen, 1943). Recent reports have recorded the isolation of P. multocida from the flicker (Wickware, 1945) and the starling, grackle, and robin (Bivins, 1953, 1955).

Rabbits are very susceptible to infection with fowl cholera organisms given per os, or by inoculation, and die from septicemic disease. White mice and field mice are also susceptible. Guinea pigs are more resistant but may succumb to intraperitoneal inoculation of P. multocida. By subcutaneous inoculation, a local abscess is produced.

Horses, cattle, sheep, pigs, dogs, and cats are refractory to infection per os, and subcutaneous inoculations result in localized abscesses. All of these animals may succumb, however, to intravenous inoculation of moderately heavy doses. Pasteurella multocida infections, usually of a localized nature, have been encountered in man, although the source of infection has generally not been determined.

Sources of infection. It is often difficult or impossible to determine how fowl cholera is introduced into a flock. Frequently it follows the addition of newly or purchased stock to the breeding flock or the addition of pullets to an older population. Free-flying birds having contact with poultry may provide a source of fowl cholera organisms.

Webster et al. (1927) examined three commercial flocks of White Leghorns for P. multocida and found that many birds harbored the organisms in the nasal clefts. Their presence was related to the amount of fowl cholera and upper respiratory infection in the flocks. They concluded that the endemic focus of infection was "healthy" nasal carriers or "roup cold" cases. In one flock, Pritchett and associates (1930 a,b; 1932) proved that "healthy" chickens saved for breeders were the reservoirs of infection. These had become carriers by having passed through an outbreak of fowl cholera the previous year. From these carriers, the organisms spread and gave rise to acute septicemic disease, localized infections, and the carrier state among contact fowls. The detection and removal of carriers resulted in effective control of the disease in the flock. Van Es and Olney (1940) studied the influence of environment on several poultry diseases and concluded that, in the transmission and dissemination of fowl cholera, apparently healthy birds as infection carriers play a dominant part. Dorsey and Harshfield (1959) reported a higher incidence of fowl cholera outbreaks during late summer and fall months in South Dakota. Carrier birds among the older flock, held over for a second year, provided a reservoir of infection for young susceptible pullets housed with them.

The body excretions of diseased birds which contaminate soil, food, or water can be an important factor in dissemination of the disease. There is evidence that nasal

excretions may have a more dominant role than feces in this regard. Contaminated crates, feed bags, or any equipment used previously for poultry may serve in introducing fowl cholera into a flock. The carcasses of fowls dead of cholera are thoroughly permeated with organisms and may serve as a source of infection, especially because of the tendency of fowls to consume such material. Reis (1931) recovered *P. multocida* from carcasses decomposed in air and in a bird exhumed eleven days after death. Hendrickson and Hilbert (1932) found the organism to remain viable for at least two months in a carcass kept in an ice box. The feeding of offal of dressed poultry is not without danger.

The possibility that insects may serve as vectors of fowl cholera has been considered. Skidmore (1932) experimentally transmitted fowl cholera to turkeys by feeding flies that had previously fed on infected blood, and cautioned that under natural conditions, ingestion of flies might be a means of introducing the disease into a flock. That such transmission is probably not common is borne out in the studies of Van Es and Olney (1910). Although virulent outbreaks of fowl cholera were maintained in two lots of chickens during the height of the fly season, there was no spread of the disease to adjoining lots separated only by poultry netting.

Natural infection and pathogenicity. Webster et al. (1927) administered stock and freshly isolated strains of *P. multocida* per os and intranasally to young and adult chickens, producing infections only in the birds exposed intranasally. They proposed that *P. multocida* infection is primarily a respiratory disease. Hughes and Pritchett (1930) again demonstrated the respiratory route of infection, with negative results by way of the alimentary canal. The response when the organisms were introduced intranasally was varied, some chickens developing acute septicemic cholera and others developing localized infections such as rhinitis and wattle involvement. Still others became healthy carriers. Webster (1930) observed that the severe epi-

demic form of fowl cholera was associated with a relatively virulent type of organism which survives with difficulty in the host, whereas the endemic disease is associated with strains of relatively low virulence and high vegetative capacity.

Cernaianu (1912) considered the fowl cholera organism a facultative pathogen, varying in virulence under different conditions of infection. He attributed the different pathological manifestations seen in fowl cholera to variation in virulence. He concluded that in order for an outbreak to occur, there must be some secondary factors such as season, weather, or nutrition.

Inadequate ventilation has also been suggested as an important contributing factor to the spread and severity of fowl cholera outbreaks. Trillat (1931) observed that mice or chickens placed in closed cages containing small quantities of culture of *P. multocida* were readily infected, provided the enclosed air was humid and contained gaseous products of respiration or solid particles. The actual number of organisms in the air required to produce disease was less than the number required for subcutaneous injection. He stated that transmission from infected to normal animals occurred in cages where there was no contact other than by air.

Pasteur (1880b) had reported that the fowl cholera organism produced toxins in culture media, and it was believed that a negative chemotaxis occurred because of this, allowing for a rapid increase of the organisms in the body. Later works of Weil (1905) and Hadley (1918) did not verify this. It is now recognized that *P. multocida* does not produce an exotoxin.

Symptoms and course of the disease. Van Es and Olney (1910) state that 4 to 9 days usually elapse before appearance of symptoms in a flock naturally exposed to fowl cholera. However, in their experimental flocks, explosive outbreaks sometimes occurred within 48 hours after the introduction of infected birds. In outbreaks of the peracute disease, premonitory symptoms may be entirely lacking, and fowls in good flesh will be found dead on the nest

FIG. 11.2 – Localized Pasteurella infection in wattle.

or beneath the perches. Similar sudden losses occur during the next few days. The rapidly mounting mortality in such flocks is good presumptive evidence of fowl cholera, especially if there are other fowl species on the premises also affected. Cyanosis of the comb and wattles is a frequent but not an invariable symptom.

Later in the progress of the outbreak, sick birds may be found which are listless, refusing to eat or drink, and staying apart from the rest of the flock on the roost, nest,

or floor. These may live for a few hours or linger for several days. Some birds living for a longer period may develop rales and a thick catarrhal nasal discharge. Diarrhea may or may not occur.

Chronic manifestations of Pasteurella infection may occur in flocks following early acute stages or in outbreaks of apparently low virulence. Localization of the organism in the wattles is common in breeds with large pendulous wattles, causing an edematous swelling, later to become caseous (Fig. 11.2). Localization in joints and tendon sheaths of the legs or wings is also common, resulting in swelling and lameness (Fig. 11.3). A few develop torticollis due to localization of P. multocida in the ear or at the base of the skull (Fig. 11.4). Outbreaks which are associated with the more chronic symptoms are prone to continue over a period of several weeks or even months.

The actual death loss in natural outbreaks of fowl cholera varies from a few birds, if brought under control promptly, to 60 per cent or more in outbreaks either of an extremely acute nature or when prolonged as a chronic disease. In chicken flocks, there are some birds which appear to resist infection throughout the outbreak. At least some of these become "nasal carriers" of the fowl cholera organism.

While the symptoms as indicated are highly suggestive of fowl cholera, confirmatory evidence is possible only by necropsy and bacteriological examination with re-

FIG. 11.3 – Localized Pasteurella infection in joint.
FIG. 11.4 – Torticollis resulting from P. multocida infection in ear.

covery of *P. multocida* from the blood or tissues.

Lesions. The lesions found on necropsy of birds dying of fowl cholera are not constant, but the pathological changes often provide suggestive evidence of the disease. In those which are found dead or died within a few hours after appearance of symptoms, petechiae and ecchymoses involving serous surfaces and the fat of the abdomen are commonly present. Hemorrhages are especially prevalent on the heart surface and gizzard (Fig. 11.5). Similar small hemorrhages may be seen in the lungs and mucosa of the intestine. Marked congestion of the duodenal portion of the intestine with a thick, viscid mucous accumulation in the lumen is a frequent postmortem finding in acute infections. In laying flocks, cheesy material from ruptured yolk sacs may be distributed in the body cavity.

The liver in acute cases reveals a parenchymatous hepatitis. The organ is somewhat swollen, of brownish or yellowish-brown color, and more friable than normal. Numerous pinpoint to pinhead size necrotic foci may be visible on the surface and distributed throughout the liver (Fig. 11.6). In infected birds which survive for several days, the liver may present a greenish color, but enlargement and necrotic foci are less frequently seen. The spleen seldom shows significant change.

In localized infections associated with the more chronic manifestations of fowl cholera, the postmortem findings are variable. Where respiratory symptoms have been predominant, a catarrhal exudate is present in the nasal passages and trachea, and solidification of parts of one or both lungs is evident in some cases. Localization in the wattles causes, at first, an edematous swelling which later is found to be a caseous exudate between the skin folds. In like manner, the exudate in tendon sheaths and joints in Pasteurella localizations may consist of a cloudy fluid or caseous exudate

FIG. 11.5 — Hemorrhages on heart, gizzard, and proventriculus in fowl cholera. (Biester, Iowa State University.)

depending on the duration of the infection. In those birds which have shown "wryneck," a caseous exudate is found in the auditory canal or involving bones at the base of the brain.

Pasteurella multocida occasionally produces localized lesions in other tissues. Thorp *et al.* (1931) observed abscesses in the oviduct, suppurative arthritis of the coxo-femoral articulation, and osteomyelitis of the proximal end of the femur in a group of spontaneously infected birds. Van Es and Olney (1940) recovered *P. multocida* from a necrotic area in abdominal fat, from a caseous plug in the ceca, and from exudate present with an infection of the oviduct.

Diagnosis. Although a presumptive diagnosis may be made from symptoms and lesions, fowl cholera must be differentiated from certain other poultry diseases,

notably fowl typhoid, fowl plague, avian monocytosis, other respiratory infections, synovitis, and localized infections from other causes. Organisms showing bipolar staining characteristics can often be demonstrated in slides smeared with heart blood or liver tissue from birds dead of acute fowl cholera. A conclusive diagnosis, however, is based on cultural methods and the identification of *P. multocida* by its biochemical characteristics.

Immunity. Pasteur (1880b), using a virulent culture of the fowl cholera organism attenuated by prolonged growth on artificial media, produced a vaccine which protected fowls against subsequent exposure. In field use, his method did not prove practical because uniform attenuation could not be secured and heavy losses sometimes occurred in vaccinated flocks. Since Pasteur's classical work, there have
FIG. 11.6 — Foci of necrosis of liver in fowl cholera. *Pasteurella* found in lesions. (Biester, Iowa State University.)

been numerous attempts to produce immunizing agents, but results have been contradictory.

Rodriquez and Antonio (1946) reviewed the literature on artificial immunization against fowl cholera and conducted immunization trials duplicating methods and procedures previously employed and commonly resorted to in practice. They used monovalent and mixed bacterins (formalin-, phenol-, and heat-killed), iodized bacterin, glycoside-lipid, natural aggressins, bacterins of soluble products of P. multocida, formalinized monovalent bacterin precipitated with sodium sulfate, and fowl cholera antiserum. None of these agents gave satisfactory immunity against fowl cholera.

Dougherty (1953) compared chemically killed broth culture bacterins with a chicken embryo culture vaccine (formalin-inactivated) in ducks. Eighty-three per cent of the ducks survived challenge with virulent culture at four weeks in the embryo vaccine group as against 17 per cent in the broth bacterin groups. By the sixth week a marked loss of immunity had occurred. Nelson (1955) obtained inconsistent results in preventing recurrence of losses from fowl cholera with autogenous bacterins in turkey flocks in field outbreaks. Heddleston and Hall (1958) conducted fowl cholera immunization trials comparing a commercial and several experimentally prepared bacterins. A water-in-oil emulsified P. multocida bacterin provided protection against challenge infection for at least 9 months and was superior to any of the other preparations used. In another experiment, a high degree of immunity was established in both chickens and turkeys with the emulsified type bacterin (Heddleston and Reisinger, 1959). An aluminum hydroxide adsorbed bacterin also produced an effective immunity for at least a year in chickens (Heddleston and Reisinger, 1960). In further studies, Heddleston (1962) noted that a P. multocida strain recovered from a fowl cholera outbreak in previously vaccinated turkeys

differed serologically and immunologically from the strain used in the preparation of the bacterin. A bivalent emulsified bacterin containing the two types (serotypes 1 and 3, Little and Lyon classification; serotypes 5:A and 8:A, Namioka and Bruner classification) stimulated and maintained a high level of immunity against both types. A bivalent aluminum hydroxide adsorbed bacterin was less effective.

Boyer and Brown (1963) were not as successful in demonstrating satisfactory immunity in turkeys following vaccination. Although bivalent commercial emulsified bacterins provided better results than monovalent bacterins, over one-third of the vaccinated birds died following challenge with a Little and Lyon type 3 culture.

Dorsey (1963b) selected strains for preparation of emulsified type bacterins from his biochemic Groups I and II. In immunization trials in chickens and turkeys monovalent bacterins provided protection at a high level against challenge with a strain of the same group. Adequate immunity was not demonstrated against challenge with a strain from the other group. However, in one trial in turkeys, the opposite was true. A Group II bacterin failed to protect against challenge by a homologous strain but good protection was provided by the Group I bacterin. He states that biochemic grouping would be useful only for roughly selecting strains for more specific serologic and immunologic identification.

Treatment. Several of the sulfonamides have been employed in treatment of fowl cholera, both experimentally and in natural outbreaks, with varying success. Sulfamethazine, sulfamerazine, and sulfaquinoxaline have received more attention than others of this group of chemotherapeutic agents. Kiser et al. (1948) reported 63 to 85 per cent reduction in mortality in experimentally produced fowl cholera compared to untreated controls, using sulfamethazine and sodium sulfamethazine. In natural outbreaks the reduction of mortality was 45 to 75 per cent. Five-tenths to

compared to 12 per cent in a group which received mash containing oxytetracycline at the level of 500 grams per ton. In six natural outbreaks, oxytetracycline at this level in the feed resulted in checking mortality, but losses recurred in three of the flocks after withdrawal of the antibiotic. In another limited trial a commercially prepared injectable form of oxytetracycline protected birds against a challenge inoculation of *P. multocida* that killed 70 per cent of a similar control group.

Prevention and control. Improved immunological agents can be valuable aids in prevention and control of fowl cholera. Recent developments in delineation of serotypes of *P. multocida* and in methods of preparation of fowl cholera bacterins are encouraging in this respect. However, good management practices must continue to be emphasized. Heddleston and Reisinger (1960) demonstrated that stresses caused by changing the social or peck order of vaccinated males and fowl pox infection in the birds at the time of vaccination and exposure significantly reduced the efficacy of vaccination.

In a management program aimed at prevention of fowl cholera, consideration must be given to the many ways that infection might be introduced and the part that carrier birds play in the dissemination of the disease. Introduction of new birds should be only as chicks and these raised in a clean environment completely isolated from mature fowls. The isolation should be continued in the housing; unless separate houses can be provided for first and second year laying flocks, the older flock should be marketed in its entirety. The separation of different species of fowls on the same premises is likewise important.

The danger of infection being introduced by cockerels or pullets acquired from other flocks or by the return of exhibition birds from fairs or poultry shows should be emphasized. Chicken crates and other pieces of equipment which have been previously used for poultry may serve as sources of infection unless they have received thorough cleaning and disinfection. The fact that *P. multocida* has been recovered from many species of free-flying birds warrants consideration of this source of infection to poultry with measures to prevent their association with the flock.

The application of strict sanitary measures both in the prevention and control of outbreaks is of utmost importance. Particular attention must be given to providing and maintaining clean litter and types of equipment for feed and water which minimize contamination with body excretions.

A practical means for the detection of carriers of the fowl cholera organism has not been developed. Shook and Bunyea (1939) reported the control of an outbreak of fowl cholera due to a carrier condition of several years' standing by means of a stained antigen, rapid whole blood agglutination test of the flock, and the removal of reactors. The stained antigen test agreed with the tube agglutination test on 133 reactor birds and negative controls. Nobrega and Bueno (1944) found that the agglutination test, performed in accordance with the technique of Shook and Bunyea, failed to reveal efficiently the fowl cholera carriers, which were identified by inoculation of pigeons and mice with mouth mucus from individuals of a flock. Dorsey and Harshfield (1959) modified the technique of preparation of an antigen for the rapid whole blood agglutination test but found poor correlation between reactions with antigens of biochemic Group I and Group II strains and isolations of *P. multocida* by nasal swabs or at necropsy in an infected flock of nearly 100 birds.

Tuberculosis of Poultry

Tuberculosis of poultry may be defined as a contagious disease caused by *Mycobacterium avium*. The disease is characterized by its insidious chronicity, its long continuation in a flock when once established, and its tendency to induce in infected birds a state of unthriftiness, decrease or stoppage of egg production, and finally death.

The announcement that tuberculosis of man and of cattle was due to a living bacterial parasite – the tubercle bacillus – was made by Koch in 1882. Tuberculosis of chickens was first recognized as a related but separate entity by Cornil and Mégnin (1884). Whether or not the microorganism of tuberculosis of chickens is identical with the microorganism responsible for tuberculosis of mammals provided much controversy. Koch (1890) maintained for many years that tubercle bacilli were always the same regardless of the species in which they might occur. However, Rivolta, and later Maffucci (1890), showed by con-

vincing experimental procedures that the microorganism of tuberculosis of chickens is definitely dissimilar to that of bovine tuberculosis. In 1901 Koch[1] finally abandoned his previous position and declared that tuberculosis of poultry is unlike tuberculosis of human beings and that the disease in man is dissimilar to that of cattle. Consequently, it was settled finally that three different species of tubercle bacilli are concerned with tuberculosis of mammals and fowl. Differences in the three species, which can be recognized readily at the present time, were vague and confused for nearly twenty years after Koch had demonstrated that a specific microorganism is the cause of tuberculosis.

Although tuberculosis of chickens had been recognized as a contagious disease even before Koch succeeded in demonstrating the tubercle bacillus, the disease has continued to spread throughout most

---

[1] Address published 1902 (Koch, 1902).

[374]

of the civilized world. With the available information on the nature of the disease, its eradication in the United States is entirely feasible. To fail to suppress the malady perpetuates an entirely unnecessary economic burden on American agriculture.

The more important reasons why tuberculosis of poultry should be eliminated may be stated briefly as follows: (1) affected birds are unthrifty; (2) tuberculous chickens are undesirable for human food; (3) diseased birds produce fewer eggs; (4) tuberculous chickens frequently are the source of tuberculosis of sheep and especially swine; and (5) avian tubercle bacilli are capable of sensitizing cattle to mammalian tuberculin.

The indictment against the tuberculous chicken is serious, and nothing has been offered to refute the fact that a tuberculous bird is an undesirable member of the farm economy and as such should be

eliminated. Unfortunately, in the United States the presence of tuberculosis of chickens continues to be accepted with a certain complacency, and we have failed as yet to formulate a comprehensive program that can be expected to eradicate the disease. The noteworthy results obtained in the program for the eradication of bovine tuberculosis should stimulate the attack on the disease in chickens.

INCIDENCE AND GEOGRAPHIC DISTRIBUTION

Tuberculosis of chickens is world-wide in its distribution; however, the disease occurs more frequently in the North Temperate Zone than elsewhere. Although the disease exists in practically all of the United States, there is a marked difference in its incidence in different parts of the country. The highest incidence of infection occurs in flocks of the western and eastern North Central States (Fig. 12.1). The states

Calendar year 1962

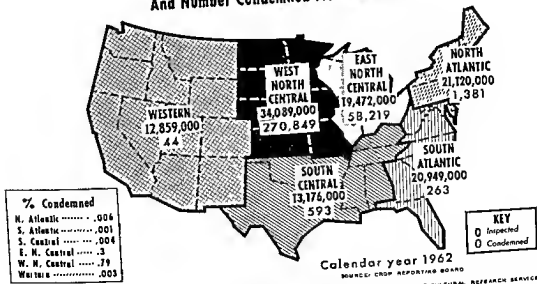
U.S. DEPARTMENT OF AGRICULTURE


FIG. 12.1 — Relative incidence of tuberculosis of poultry in the United States based on data compiled by the Agricultural Research Service, USDA. Note that the highest percentage of condemnations for tuberculosis for the year 1962 was among chickens in six states, comprising the West North Central area, the lowest percentage of condemnations was in chickens in the 11 states designated "Western." (Courtesy of Dr. A. F. Ranney, Chief, Tuberculosis Eradication Section, USDA.)

in which the disease is most prevalent include North Dakota, South Dakota, Kansas, Nebraska, Minnesota, Iowa, Missouri, Wisconsin,[2] Illinois, Michigan, Indiana, and Ohio. Although no data are available as to what percentage of individual chickens in the states just mentioned are tuberculous, there are available figures that indicate that in some areas more than 50 per cent of the flocks may be infected. The incidence of the disease in the western and southern states is quite low. The explanation for this is not entirely obvious, although there are several possible contributing factors such as climate, flock management, and duration of the infection. The maintenance of large flocks in the north central part of the United States and the necessity, for climatic reasons, to keep the birds closely confined during winter months provide favorable conditions for the spread and continuation of the disease.

The difficulty of tuberculin-testing all chickens in the United States, or of testing even a majority of the flocks, makes it impossible to obtain exact data on what the incidence of tuberculous infection of chickens really is. However, figures are available as a consequence of various surveys that indicate in a general way the extent of the infection. Information obtained from such sources suggests that the over-all incidence of tuberculosis in poultry for the entire United States is gradually receding and is probably less than 5 per cent.

These figures may be misleading unless it is remembered that the incidence of infection varies greatly in different sections of the country. In the heavily infected western North Central States, where the disease is most prevalent, a conservative estimate would place the percentage of flock infection in some areas as high as 50, whereas in the northern Atlantic States, the southern Atlantic States, the South Cen-

tral States, and the western states, the percentage of infection is negligible (Fig. 12.1). The infection rate varies greatly for individual flocks in the United States, from less than 5 per cent to as much as 95 per cent.

How reliable data may be as indicative of the exact situation regarding the prevalence of avian tuberculosis throughout the entire United States is difficult to appraise. If there has in fact been a significant reduction in the prevalence of the disease, it is probably due in considerable part to the changing concept of poultry husbandry. During the past several years increasing emphasis has been placed on the commercial desirability of young rather than adult birds. However, it is not likely that the prevalence of the disease has changed appreciably among long-established farm flocks where poultry is maintained more or less incidental to general farming operations.

As in the United States, the incidence of tuberculosis of chickens varies greatly in the different areas of Canada. From available data the incidence of infection in the different provinces varies from 1 per cent to 26 per cent. The disease occurs to only a limited extent in the Panama Canal Zone and has been observed but infrequently in Chile, Cuba, and Puerto Rico. The disease has not been reported from Colombia.

Considerable information concerning the incidence of avian tuberculosis in Europe is available. In Bulgaria the incidence of the disease is relatively low. The disease is rather prevalent in England and to probably a less extent in Scotland. Adequate information regarding the incidence of the disease in France is not at hand. However, the disease does exist in that country. Data from German sources prior to World War II indicate that avian tuberculosis was extremely prevalent in the German Reich and that the disease constituted a serious handicap to the poultry industry of that country. Tuberculosis of chickens is practically unknown in Greece, infrequent in Switzerland, and apparently of rare oc-

---

[2] According to Hastings and Halpin (1913), tuberculosis was not recognized by the Agricultural Experiment Station of Wisconsin as occurring in poultry flocks of that state prior to 1906

currence in Italy. The disease occurs in Spain and seems to have assumed serious proportions in certain of the Baltic States. Avian tuberculosis is of frequent occurrence in certain districts of Norway. The disease occurs in Holland and is apparently on the increase in Czechoslovakia and Bessarabia.

Avian tuberculosis has been observed in a few instances in Indonesia, but it is apparently rare or nonexistent in the Philippines and in the state of Israel.[2] The disease has been noted in the Union of South Africa and in New Zealand. In China there is a question whether the disease exists at all, although in Mukden there is evidence that the infection is fairly common.[4]

Age in relation to incidence. Aside from the influence of climate and the factors of environment, the incidence of infection also depends upon the age of the chickens. This is well illustrated by the following data.[5] Twenty-eight farm poultry flocks in one county in Illinois were tuberculin-tested, and fourteen, or 50 per cent of the flocks, were found to contain tuberculous birds. In these flocks the incidence of tuberculosis among a total of 1,476 hens more than one year of age was 11.1 per cent. In 1,056 pullets (less than one year of age) in the same flocks, the incidence of infection as determined by the tuberculin test was 0.19 per cent. Hays (1929) found among 40,073 chickens tested in Nebraska that the incidence of tuberculosis was 9.3 per cent. When the tuberculous birds were considered in relation to the different age groups, it was found that 77.6 per cent of the infected chickens were more than one year of age and 22.4 per cent were one year of age or less.

These data confirm the view that tuberculosis becomes more prevalent as the ages of the birds advance. There is evidence that indicates, however, that infection is less likely to succeed if exposure is delayed until the chickens reach the state of maturity, and that the disease when present in adult birds represents in most instances a process that began months or even years before, when the animal was young. Tuberculosis appears to be less prevalent in young fowl than in older ones, not because the younger are more resistant to infection than the older, but because in the older birds the disease has had a greater opportunity to become established as a consequence of a longer period of exposure.

Although the lesions of tuberculosis in young chickens are usually less severe than the lesions in the adult, extensive or generalized tuberculosis in young chickens has been observed occasionally. Such an animal obviously constitutes an important source of dissemination of virulent tubercle bacilli and must be considered a menace to other fowl and to susceptible mammals. That generalization of the disease does occur in young birds provides a formidable argument against the claim that avian tuberculosis can be eliminated by disposing of the older hens and maintaining a flock of young birds only. It is true that the concentration of potentially infective materials will be diminished eventually if only young birds constitute the flock, but if the flock is maintained on contaminated premises new infections are likely. The presence of even one pullet that has lesions along the intestinal tract will provide an adequate source of tubercle bacilli to insure the continuance of the disease.

THE CAUSATIVE AGENT[6]

Morphology. The agent responsible for avian tuberculosis is a member of the genus *Mycobacterium* and is known correctly as *Mycobacterium avium*. The most characteristic feature of the organism is its acid-

---

[2] According to Dr. J. Van der Hoeden, Director of Veterinary Institute, Tel-Aviv, tuberculosis does not exist among chickens in Israel (personal communication to the author, 1951).

[4] For a more detailed account of the occurrence of tuberculosis in chickens in various parts of the world, consult the monograph by Feldman (1938).

[5] Information supplied many years ago by the late H. R. Smith, Livestock Commissioner, National Livestock Exchange, Chicago.

[6] Methods for the isolation and culture of tubercle bacilli are given in detail in a monograph on avian tuberculosis infections (Feldman, 1938).

fastness.[7] The organism is capable of considerable pleomorphism, this feature being dependent on the character and chemical composition of the medium on which the bacteria are grown. While the organisms are bacillary in character, with perfectly straight forms usually present, clublike, curved, and crooked forms are also usually seen in most preparations. Branching infrequently occurs. Most of the bacteria have rounded ends. The bacteria vary in length from 1 to 3μ, and the average length has been determined to be 2.7μ. Spores are not produced, and the organism is nonmotile.

Reproduction of the avian tubercle bacillus is by simple fission. The existence of a filter-passing form of the avian tubercle bacillus has not been established. Spherical or conical granules occur in the endoplasm. These usually occur anywhere along the length of the bacterium. Whether or not the avian tubercle bacillus is capable of giving rise to forms comparable to Much's granules is uncertain. Although the avian tubercle bacillus will grow and retain its virulence under a variety of atmospheric conditions, the organism is generally considered as aerobic.

The avian tubercle bacillus is not as exacting in its temperature requirements as are the human and the bovine forms of the organism. The avian form of the bacillus will grow at temperatures ranging from 25° to 45° C., although the most

[7] The Ziehl-Neelsen method of staining tubercle bacilli:

1. Cover a fixed film or smear preparation with Ziehl-Neelsen's carbolfuchsin (prepared by adding 10 cc. of a saturated alcoholic solution of basic fuchsin to 90 cc. of a 5 per cent aqueous solution of phenol). Steam gently but continuously for 2 minutes.

2. Wash in water and decolorize with methylene stain by applying an excess of acid alcohol (prepared by adding 2 cc. of hydrochloric acid to 98 cc. of 80 per cent alcohol). Decolorization should be complete in 10 to 20 seconds.

3. Wash in water and counterstain with Löffler's methylene blue for 3 to 5 seconds.

4. Wash in water and dry. Examine with the oil immersion lens.

Tubercle bacilli and other mycobacteria stain bright red; other microorganisms stain blue.

favorable temperature is between 39° and 40° C.

Cultural distinctions. The avian tubercle bacillus is not a difficult organism to cultivate artificially. Stock strains will grow on most solid mediums although for original isolation of the organisms from naturally infected material one of the special mediums designed for culturing tubercle bacilli is desirable. Glycerinated or nonglycerinated mediums are satisfactory, but the resultant colonies are larger if the medium contains glycerin than if it does not. After a culture has been obtained on solid mediums, subcultures usually will succeed in liquid mediums.

On mediums containing whole egg or egg yolk seeded with material prepared from tuberculous tissue and incubated at 37.5° to 40° C., the bacteria usually will become evident in 10 days to 3 weeks as small, slightly raised, discrete, grayish-white colonies (Fig. 12.2). If the inoculum is rich in bacteria, the resultant colonies will be numerous and may tend to coalesce into granulated masses, but there is slight, if any, tendency for the individual colonies to spread. The colonies are hemispherical and do not penetrate into the substance of the medium. If the medium contains glycerin, the colonies gradually change from grayish-white to light ocher. The color becomes darker as the age of the culture increases.

Subcultures on solid mediums show evidence of growth within a few days and reach a maximal development in three to four weeks. Such cultures usually appear moist and unctuous, the surface eventually becoming roughened. The growth is translucent and has a creamy or sticky consistency; it is readily removable from the underlying medium.

Other biochemical characteristics of *M. avium* are: test for niacin is negative, high catalase content, test for peroxidase usually negative, and failure to hydrolyze Tween 80.

In liquid mediums, such as glycerinated broth, growth occurs at the bottom as well

FIG. 12.2 — *Mycobacterium avium*. Primary isolation cultures showing the enhancement of growth in the presence of glycerin (two slants at left) in comparison with growth on nonglycerinated medium (two slants at right).

as at the surface. The surface growth is represented by a delicate filmy pellicle which, as growth continues, becomes thickened, slightly wrinkled, and granular. A "ring" of growth extending upward from the surface often occurs on the inner wall of the flask. Even after prolonged incubation, if the growth is not contaminated, the medium remains clear. The growth finally becomes golden yellow and gives off a characteristic odor.

Although most strains of *Mycobacterium avium* are smooth and moist when first isolated, cultures of avian tubercle bacilli have been noted that were rough, dry, and crumbly. The occurrence of such strains is sufficient reason for caution in designating the type of any tubercle bacillus without tests for pathogenicity.

In vitro, the avian tubercle bacillus is capable of dissociation. By this phenomenon marked variations in the physical character of the colonies become evident. The following variants have been noted: "S" or smooth, which produces a raised, smooth, moist growth; "FS" or flat and smooth, in which the growth is slightly wrinkled and moist and in which the colonies are larger than those of the "S" variant; "R" or rough, in which the colonies are large, dry, and wrinkled; and "CH" or chromogenic. The last-named is physically not unlike

the "S" variant except that the colonies become ocher.

In addition to the physical differences between the variants, there also exist antigenic and pathogenic differences that are significant to a thorough understanding of the variation that occurs after natural infection with the avian tubercle bacillus. Experimentally, it has been noted that the "S" variant is far more pathogenic than the markedly dissimilar "R" variant, whereas the "CH" variant is essentially avirulent.[3]

Stability of types. Although nearly all strains of avian tubercle bacilli possess the essential cultural and pathogenic characteristics necessary to distinguish this organism from the other species of mycobacteria, occasionally strains have been encountered that appear to be atypical. The most likely explanation for the occurrence of such strains is that they represent variants that are themselves unstable. Some contend that the respective types of tubercle bacilli are not necessarily stable and that transmutation of one type into another may occur as a consequence of environmental adaptation. This is a controver-

[a] A more complete discussion of dissociation and colony variation will be found on page 50 of the monograph on avian tuberculosis infections (Feldman, 1938).

sial question, and while it remains unsettled the balance of evidence is strongly on the side of stability.[9]

Antigenic properties. Although the human and the bovine forms of the tubercle bacillus are serologically indistinguishable by either the agglutination or the complement-fixation reaction, the antigenic structure of the avian tubercle bacillus is unlike that of the mammalian forms and may be distinguished from the latter by agglutinin absorption. However, avian tubercle bacilli do not constitute a homogeneous group. There exist at least three avian subtypes that can be distinguished serologically.[10] Distinguishing precipitins have not been demonstrated.

Sensitivity in vitro to certain antimicrobials. The antimicrobial sensitivity of a strain of biologically proven M. avium isolated from a patient affected with pulmonary silicosis was reported by Karlson and associates (1955). It was determined that the microorganisms were resistant to 10 but not to 50 micrograms of streptomycin, to more than 10 micrograms of para-aminosalicylic acid, and to more than 40 micrograms of isoniazid per milliliter of medium, respectively. It was mentioned that the respective sensitivities recorded for the three antimicrobials were characteristic of avian tubercle bacillus.

CHEMISTRY OF THE AVIAN TUBERCLE BACILLUS[11]

The avian tubercle bacillus contains carbohydrates, lipids, and proteins, all of which, according to Sabin (1932), play a part in the cellular reactions of tuberculosis. Some of the carbohydrates are readily extractible; others occur in chemical com-

bination as, for example, the polysaccharides, manninositose, and trehalose, which are esterified with fatty acids. Renfrew (1929) has studied the carbohydrates which may be extracted with water from the defatted cells. The fraction, 1.4 per cent of the defatted cells, which may be precipitated with basic lead acetate, is smaller than the similar fraction from tubercle bacilli of the human type. Chargaff and Moore (1944) have isolated glycogen from avian tubercle bacilli by high-speed centrifugation. Renfrew reported the presence of about 10 per cent nitrogen in the defatted cells, of which 4.4 per cent is in water-soluble protein which possesses the characteristic biological activity of tuberculin, and 34 per cent is in protein, soluble in dilute alkali, with a much larger quantity remaining undissolved. Using another procedure, Menzel and Heidelberger (1938) isolated four fractions of proteins which gave a total of 14.2 per cent protein in the dried defatted cells. By serologic experiments, they demonstrated definite differences in specificity between the protein fractions of the avian and the corresponding protein fractions of the human and bovine types of tubercle bacilli.

The lipids of the tubercle bacilli have been studied extensively by Anderson (1942) and co-workers. With mild methods of extraction they (Anderson et al., 1930a and b) found the lipid content of dried avian tubercle bacilli to be 15.26 per cent; by more vigorous extraction, they (Anderson et al., 1940) obtained an additional 10.8 per cent of firmly bound lipids. The lipids that are extracted by the mild treatment are phosphatides, acetone-soluble fat, and chloroform-soluble wax. The avian tubercle bacillus contains smaller quantities of phosphatides and acetone-soluble fat and a much larger quantity of the firmly bound lipids than does the human type tubercle bacillus.

Like other tuberculophosphatides, those from avian tubercle bacilli contain low percentages of phosphorus and nitrogen (Anderson et al., 1930a and b). The fol-

---

[9] Observations on what appeared to be a temporary modification of avian tubercle bacilli in naturally infected crows were reported by Mitchell and Duthie (1950) and in wood pigeons (Columba palumbus) by McDiarmid (1948).

[10] For a detailed account of the antigenic features of M. avium determined serologically, the report by Rotach (1947) may be consulted.

[11] This section was kindly prepared by Dr. Eunice V. Flock, Mayo Graduate School of Medicine, Rochester, Minnesota.

lowing fatty acids are found: palmitic, stearic, oleic, and a new group of saturated liquid fatty acids. The fatty acids are esterified with manninositose instead of glycerol. The saturated liquid fatty acids resemble tuberculostearic acid from the human strain in their biological activity. In the neutral fat, the fatty acids are esterified with trehalose.

The crude chloroform-soluble wax extracted from the tubercle bacillus accounted for 70.7 per cent of the total lipids (Anderson and Roberts, 1930a). The wax contained two optically active hydroxy acids or mycolic acids of high molecular weight which had the property of acid fastness (Anderson and Creighton, 1939). Trehalose and d-eicosanol-2 were also found in the wax. Later two waxes C and D were described. Wax C consists mainly of unusually long chain fatty acids which are esterified with polyhydroxy compounds such as phthiocerol, glycerol, and trehalose to form lipids of relatively high molecular weight, ranging from 1000 to 5000 (Noll, 1957; Miquel et al., 1963). Wax D contains high molecular lipopolysaccharides including 4 mycolic acids, galactose, glucose and arabinose.

Specific glycolipids called mycosides (Smith et al., 1960) have been found in ethanolether extracts of tubercle bacillus. Mycoside C produced by Mycobacterium avium differs from other mycosides in that it contains a peptide. Three different amino acids, D-phenylalanine, allo-threonine, and D-alanine are linked in a pentapeptide. The sequence of amino acids has been determined (Jollès et al., 1961). A mixture of unsaturated hydroxy acids and two molecules of acetic acid are also present in mycoside C. Individual strains of Mycobacterium avium appear to produce mixtures of glycolipids with the same monosaccharide units but it is possible that variation occurs in the proportion and types of monosaccharides from strain to strain (MacLennan, 1962). Eight sugars have been isolated from mycoside C, glucose, arabinose,

rhamnose, 3-0-methylrhamnose, 2,3 and 3,4-0-methylrhamnose, 6-deoxytalose, and 3-0-methyl-6-deoxytalose.

Konno (1956) has shown by a direct qualitative chemical method that M. avium does not synthesize nicotinic acid. A modification of this test by Runyon et al. (1959) is recommended.[12]

SUMMARY OF DISTINGUISHING FEATURES

The more essential features that distinguish avian tubercle bacilli from the human and bovine forms of the organism are summarized in Table 12.1. Although in most instances differences in the physical properties are sufficiently impressive to separate the avian from the mammalian forms of the tubercle bacillus, in critical work in which convincing proof of identification is desirable the animal inoculation method is the procedure of choice. In other words, pathogenic behavior is more important than physical characteristics in revealing whether or not an acidfast organism is the avian, human, or bovine form of the tubercle bacillus.

PATHOGENICITY FOR OTHER FOWL

All species of birds are capable of being infected with avian tubercle bacilli. Some species are more susceptible than others, and generally speaking, those that are domesticated are affected more frequently than those living in a wild or free state. Among the domesticated fowl other than chickens in which tuberculosis may occur are ducks, geese, swans, peacocks, and turkeys. Although tuberculosis occasionally develops in domestic pigeons as a consequence of infection with avian tubercle bacilli, there is evidence that pigeons are more resistant to the infectious agent than are chickens. Parrots and canaries may be

TABLE 12.1
SUMMARY OF ESSENTIAL DIFFERENCES BETWEEN AVIAN, HUMAN,
AND BOVINE FORMS OF THE TUBERCLE BACILLUS

	Avian	Human	Bovine
Growth in egg medium (without glycerin)	Grows readily. Culture moist and unctuous Optimal temp. 40° C.	Grows well. Culture dry and roughened. Optimal temp. 37.5° C.	Grows slowly. Culture thin and without pigment. Optimal temp. 37.5° C.
Growth in liquid medium	Pellicle formation with crumbly granular growth at bottom	Pellicle formation with growth limited to surface	Pellicle formation with growth limited to surface
Miscibility with saline solution	Suspension easy. Organisms uniformly distributed	Suspension difficult. Organisms form clumps	Suspension difficult. Organisms form clumps
Tuberculin sensitivity	More intense for homologous tuberculin	More intense for mammalian tuberculin	More intense for mammalian tuberculin
Pathogenicity*	Virulent for chickens and rabbits Slightly pathogenic for guinea pigs	Nonpathogenic for chickens. Markedly virulent for guinea pigs but only slightly so for rabbits	Nonpathogenic for chickens. Markedly virulent for guinea pigs and rabbits

* When testing tubercle bacilli for pathogenicity, chickens and rabbits should be inoculated intravenously; guinea pigs, subcutaneously

infected with avian tubercle bacilli, but it is the general impression that these species are less susceptible to avian tubercle bacilli than to the mammalian forms of the organism. Naturally acquired *M. avium* infection in a small flock of Muscovy ducks, and human type tuberculosis in an Amazon parrot, presumably acquired from a tuberculous person, were reported by Hinshaw (1933a and b).

Among wildfowl, tuberculosis is uncommon. However, in wild birds that frequent farm premises where tuberculosis is prevalent in chickens, the disease may be expected to develop. Pheasants *seem to be* markedly susceptible to infection by the avian tubercle bacillus, and the disease has also been observed in the sparrow, the crow,[13] the barn owl, the cowbird, the

blackbird, the eastern sparrow hawk, and the wood pigeon.[14]

Tuberculosis is common among birds in many zoological gardens. In the unnatural environment of captivity, the incidence of the disease frequently equals or even exceeds that for the domestic species of fowl. The infectious agent in practically all instances is the avian tubercle bacillus, although a few instances have been reported of birds being infected with heterologous strains of tubercle bacilli. Tuberculosis in the parrot is usually due to either the human or the bovine type of bacillus.

Some years ago, Ratcliffe (1946) presented convincing evidence that frequency

---

[13] Mitchell and Duthie (1950) reported tuberculosis in 9.5 per cent of 263 crows (*Corvus brachyrynchos*). The birds were obtained from western and from northwestern Ontario. Of the 25 infected crows observed, tuberculosis lesions occurred in the livers of 23, in the spleens of 8, in the lungs of 2, and elsewhere in 4.

[14] Some years ago, a mycobacterial, tuberculosis-like disease of the migratory wood pigeon (*Columba palumbus*) was reported from Denmark by Christiansen et al. (1946). Later, what appeared to be a similar condition was reported in England by McDiarmid (1948). The Danish workers failed to transmit the infection experimentally, or to culture the organism artificially, whereas McDiarmid succeeded in culturing the organism and observed a restoration of virulence after serial passage *in vivo*.

TABLE 12.2

COMPARATIVE PATHOGENICITY OF *Mycobacterium avium* FOR CERTAIN MAMMALS

Animal	Susceptibility	Animal	Susceptibility
Cat	Highly resistant	Marsupials	Infection reported
Cattle	Infection occurs; usually localized	Mink	Readily infected
Deer	Infection reported	Monkey	Highly resistant
Dog	Highly resistant	Mouse	Relatively resistant
Goat	Assumed to be relatively resistant	Rabbit	Readily infected
Guinea pig	Relatively resistant	Rat	Relatively resistant
Hamster	Susceptible (intratesticularly)	Sheep	Moderately susceptible
Horse	Assumed to be highly resistant	Swine	Readily infected
Man	Highly resistant		

of incidence of tuberculosis in captive wild birds was related to dietary factors that are remediable. Following the change of diet, to provide adequate protein, vitamin B complex elements, vitamins A and D, and iodized salt, the frequency of the disease in the bird collection of the Philadelphia Zoological Garden was reduced significantly.

PATHOGENICITY FOR MAMMALS[15]

The bacterium responsible for tuberculosis of fowl has a definite pathogenicity for some important species of domesticated mammals and at least a slight pathogenicity for others. This fact should be recognized more widely if the problem of eliminating tuberculosis infections is to be attacked intelligently and eventually solved.

Under conditions of natural exposure it is very exceptional for aggressive, extensive tuberculosis to develop in mammals other than rabbits and swine as a consequence of avian tubercle bacilli. Infection may occur, but the disease remains benign and localized. However, the microorganisms may assume a parasitic existence and multiply in the tissues for a considerable period and, in some instances, may induce a state of sensitivity to tuberculin even though recognizable alterations in the tissues cannot be found (Feldman, 1960). Although spontaneous infection of mammals fails in most instances to produce a disease of comparable severity to that which develops in fowl infected with avian tubercle bacilli, it is possible to produce extensive changes in many species of mammals by introducing the infective agent artificially. The relative pathogenicity of *M. avium* for many of the domesticated mammals is summarized in Table 12.2.

Cattle. Concerning the ability of avian tubercle bacilli to infect cattle, the significant information may be summarized as follows: (1) Avian tubercle bacilli have at least a limited pathogenicity for cattle. (2) The morbid changes produced are inclined to remain localized. Whether or not avian tubercle bacilli are ever responsible

for destructive, widespread, or generalized tuberculosis in cattle is not definitely known.[16] (3) The avian tubercle bacillus is apparently capable of parasitic existence in the tissues of cattle without necessarily giving rise to recognizable tissue changes. However, when lesions occur they show the structural changes ordinarily associated with tuberculosis. (4) Following natural exposure to avian tubercle bacilli, cattle may become sensitized to avian tuberculin, and some of the animals may react to mammalian tuberculin also. (5) The interpretation of the tuberculin test in cattle is made more difficult and uncertain if tuberculous swine or poultry exist on the same premises (Feldman, 1960).

Swine.[17] In an infected environment swine readily become infected with avian tubercle bacilli. Since the beginning of federal supervision of abattoirs in the United States, it has been noted that the incidence of tuberculosis in swine exceeds that in cattle. For example, among approximately 67.1 million swine slaughtered and federally inspected during the fiscal year ending June 30, 1962, parts or the entire carcasses of 1.51 million or 2.25 per cent of the animals were found to be tuberculous. This is in marked contrast to the incidence of tuberculosis in cattle. During the same period of time, the carcasses of approximately 20.1 million cattle were examined post mortem and tuberculosis was found among 1,979 or .01 per cent.[18] The ratio of the occurrence of in-

fection for the two species was 225 to 1.

The explanation for the marked difference in the incidence of tuberculosis in swine compared to that in cattle became apparent many years ago when it was established that more than 80 per cent of the infections in swine were due to the bacillus of avian tuberculosis. Furthermore, it was recognized that a significant correlation existed between the incidence of tuberculosis in swine and the frequency of the disease in poultry in the areas where the infected swine originated.

The fallacy of expecting tuberculosis of swine to disappear with the elimination of the disease in cattle is obvious. Tuberculosis will remain an unnecessary economic burden on swine husbandry until the disease is eliminated from chickens and other barnyard poultry. That the incidence of tuberculosis in swine in the United States is gradually but definitely lessening is indicated in Table 12.3.

Human beings.[19] The literature contains a considerable number of instances in which it was claimed that avian tubercle bacilli were responsible for a tuberculous infection in human beings. Very few of the published reports of such cases contain unequivocal proof necessary to substantiate the contention that avian tubercle bacilli were the agents responsible for the condition described. As a matter of fact, in only a relatively small number of instances has the evidence necessary to prove an avian type of infection in man been presented.[20] The rarity of such cases can only indicate that human beings are extremely resistant to this form of the tubercle bacillus.

[16] Timoney (1939) reported an instance in which tubercle bacilli proven by proper tests of pathogenicity to be avian were obtained from the tuberculous udder of a 7-year-old cow. The report also includes a valuable review of the literature pertaining to infection of cattle by the organisms of avian tuberculosis. Fincher et al. (1954) reported an instance of avian tuberculous infection of the cerebral and spinal meninges and the uterus of a 3 year-old Guernsey cow.

[17] For a detailed account of tuberculosis of swine, the report by Karlson (1961) may be consulted.

[18] [Agriculture Department] Meat Inspection Division, Agricultural Research Service, U.S.D.A. Agricultural Research Service 93-2-6. U.S. Government Printing Office, Washington, D.C. (1962).

[19] Detailed accounts of avian tuberculosis infections in human beings have been published previously by Fontana (1935), Feldman (1938 and 1947), and Rich (1951). Also see Table 12.2.

[20] Several proven cases of infection of human beings with avian type tubercle bacilli have been reported during the past few years. For details see Bradbury and Young (1946), Finlayson (1948), Dragstedt (1949), Karlson and associates (1953, 1955), Furniss et al. (1961), and Cheung and Konst (1965).

SOURCES OF INFECTION

In most instances the presence of tuberculosis in a farm flock can be explained by the fact that the flock is maintained in an unhygienic environment where infected birds have been kept for many years previously. Of course the introduction of new adult stock from sources where tuberculosis exists is a hazardous procedure and may be the means of transmitting the disease to a previously healthy flock. When new flocks are to be established from sources other than hatcheries, it is exceedingly important that the new stock be from sources where it is definitely known that tuberculosis does not exist. Another possible source of infection is uncooked garbage that may contain the offal of tuberculous fowl and trimmings from tuberculous swine carcasses in which the infectious agent was the avian tubercle bacillus.

Chicks hatched from eggs laid by hens naturally infected with tuberculosis are believed by some to constitute a factor in the transmission of the disease. However, at the present time there is no convincing evidence that tuberculosis is likely to be introduced into a flock in this manner. In other words, baby chicks, regardless of their

maternal source, if reared in an environment free from tubercle bacilli, are unlikely to become tuberculous.[21]

SYMPTOMS IN CHICKENS

In attempting to recognize tuberculosis in the living bird, it should be borne in mind that but few symptoms of the disease are truly pathognomonic. From a practical point of view, probably the most expedient way of diagnosing the disease with certainty is by postmortem examination. The lesions are fairly characteristic and not likely to be confused with other pathologic conditions. However, tuberculous fowl do manifest certain symptoms that, when considered with other factors, constitute presumptive evidence of the disease. It is seldom that any one infected bird will present all the symptoms that have been considered indicative of infection. However, if the disease be at all prevalent in a flock, several or most of the symptoms may be evident in different birds.

Since tuberculosis usually has a protracted course, the disease is more likely to be

* In Norway, where tuberculosis is rare, the disease has been found in migrant wild birds; such birds may account for outbreaks of avian tuberculosis in swine and poultry in that country (Høybråten, 1959).

FIG. 12.3 – Carcasses of three tuberculous chickens from a flock in which the disease was rampant. Note the extreme atrophy of the muscles of the breast.

detected during life by careful and repeated examination than by a single cursory inspection. The incubation period is usually long, and since objective signs are absent in the early stages of the disease, it is usually not possible to diagnose the malady at that time unless resort be had to the tuberculin test.

Ordinarily, if the disease has progressed sufficiently to affect the physical condition of the bird, the animal will be less lively than its mates. If the disease is in an advanced stage the affected fowl fatigues easily and appears depressed or languid. Although the appetite usually remains good, there commonly occurs a progressive and striking loss of weight which often amounts to emaciation. The thinness of the tuberculous bird is especially noticeable in the muscles of the breast (Fig. 12.3). The pectoral muscles are often in a state of complete atrophy, and as a consequence the keel or breast bone becomes strikingly prominent and may be deformed In extreme instances most of the body fat eventually disappears, and the face of the affected bird appears smaller than it would normally

As the disease progresses the feathers assume a dull and ruffled appearance. The comb, wattles, and ear lobes often become anemic and thinner than normal, and the uncovered epidermis has a peculiar dryness. Occasionally, however, the comb and wattles have a bluish discoloration. Icterus, indicative of hepatic changes, may be noted.

Unlike tuberculous infections in many of the mammals, and contrary to the opinion of some writers, the disease in chickens apparently does not induce a febrile state. Even though the disease is most severe, the temperature of the affected bird remains within the normal range. In many instances the bird, when forced to move, reveals a unilateral lameness and walks with a peculiar jerky, hopping gait. This alteration of the gait, which appears to be characteristic, is probably due to tuberculous involvement of the bone marrow of the leg. Infrequently a wing may droop as though paralyzed, owing to a

tuberculous involvement of the bumeral scapulocoracoid articulation. The lesion in this situation may rupture and discharge thin or caseous material. Paralysis due to tuberculous arthritis sometimes occurs, but this is not a frequent symptom of the disease.

If the affected chicken is greatly emaciated, one may detect nodular masses along the intestine by palpation of the abdomen. The great hypertrophy of the liver of many tuberculous birds, however, may make this procedure difficult or impossible. In about 10 per cent of tuberculous chickens, one may recognize the disease by palpation of the involved thymus glands. The crop should be empty if this procedure is to yield satisfactory results.

Most tuberculous chickens have lesions along the intestinal tract, and if these be ulcerative, as they usually are, severe diarrhea that is usually unmanageable results. The enteric disturbance induces an extreme weakness, and the affected bird assumes a sitting position as a result of exhaustion.

The duration of life of the tuberculous chicken is variable. Affected birds may die within a few months or may live for years, depending on the severity or extent of the disease. Death may occur from sheer exhaustion, or the affected bird may die suddenly as a consequence of hemorrhage from rupture of the affected liver or spleen.

But few of the symptoms given are necessarily characteristic of tuberculosis. Convincing proof of a tuberculous infection can be obtained best by necropsy. In fact the importance of necropsy for establishing a diagnosis of tuberculosis in chickens cannot be overemphasized. However, in districts where tuberculous poultry exists, the presence of the disease is suggested by (1) unthriftiness, (2) progressive loss of flesh in spite of good appetite, (3) the chronicity of the symptoms, and (4) the occurrence of the disease in swine not exposed to mammalian tubercle bacilli.

Since the presence of tuberculosis does not preclude the co-existence of other diseases, there are certain conditions that must be differentiated from tuberculosis. These include neoplasia (tumors), tapeworm infection, enterohepatitis, and certain arthritic conditions such as may be associated with fowl cholera, fowl typhoid, paratyphoid, or gout. From the standpoint of the pathologic findings, two facts should be borne in mind in distinguishing tuberculosis from other conditions of chickens. These are (1) the character and distribution of the lesions in the abdomen, associated in a large percentage of cases with lesions in the bone marrow, and (2) the presence within the morbid tissues of numerous acid-fast bacilli. The latter are especially significant since they do not occur in any other spontaneous disease of chickens.

THE TUBERCULIN TEST

At present the method of choice for determining the presence of tuberculosis in the living chicken is the intradermal tuberculin test, which was first applied successfully to chickens by Van Es and Schalk (1914). When it is administered properly and the results are interpreted with understanding, the tuberculin test provides a satisfactory procedure for determining whether or not tuberculosis is present in a given flock. The test is not infallible, but in the hands of one competent to administer it and to interpret the results properly, the procedure offers an extremely valuable aid in the diagnosis and control of avian tuberculosis.

Technique of test. The equipment necessary consists of a sterile tuberculin syringe of the Luer type of 1 cc. capacity and a goodly supply of sterile hypodermic needles one-half inch (1.3 cm.) in length and of 25 to 26 gauge. Absorbent cotton and a few fluid ounces of 70 per cent alcohol should also be available. The tuberculin to be used should be that prepared for intradermic use from avian tubercle ba-

FIG. 12.4.— Positive reaction in left wattle of a tuberculous chicken 48 hours after intracutaneous injection of avian tuberculin.

cilll.[22] The bird should be restrained so that the head is entirely immobile. The site of injection is the wattle. If soiled, the surface of the wattle should be cleaned with alcohol; otherwise, cleaning or attempting to disinfect the skin is unnecessary. The operator grasps the wattle between the thumb and forefinger of one hand, and with the other manipulates the syringe containing the tuberculin. The needle of the syringe then is inserted carefully into the lateral aspect of the dermis, and 0.03 to 0.05 cc. of tuberculin is forced into the tissue. If the procedure has been accomplished properly, a small bleb or a small diffuse blanched area will appear where the tuberculin was deposited. Although fairly satisfactory results may follow if the tuberculin is injected into the subcutaneous tissue, it is a better practice in all instances to place the tuberculin intradermally.

* Tuberculin prepared from mammalian strains of tubercle bacilli may elicit positive reactions in tuberculous chickens, but the results are generally unsatisfactory. More infected birds will be revealed with the avian product, and the reactions to avian tuberculin are usually more pronounced than those elicited with mammalian tuberculin.

The reaction. After 48 hours the chickens are examined and the results recorded. Using for comparison the opposite uninjected wattle, positive reactions are usually easy to recognize, although much experience and a thorough understanding of all factors involved are essential if the results are to be evaluated properly. A positive reaction is indicated by the presence of a soft swelling in the tissues of the injected wattle (Fig. 12.4). Not all reactions are of equal magnitude; some are small, and some result in a pronounced swelling which increases the thickness of the wattle one to five times. The swelling is due largely to edema which occurs in the zone of the connective tissue which lies between the layers of the reflected dermis. To a lesser extent the swelling is due to the increased width of the corium, which is filled with closely packed mononuclear histiocytic cells, a few eosinophilic granulocytes and a variable number of lymphoid cells and lymphocytes (Fig. 12.5). If the reaction is severe the cellular response occurs throughout the corium of the entire wattle. Necrosis of the tissues overlying the site of reaction rarely, if ever, occurs. Hyperemia of the region of the reaction is not apparent, and the swollen wattle is usually grayish or pale yellow. After 48 hours the swelling gradually subsides and usually disappears within 5 days after the tuberculin was injected.

Certain aspects of the test may occasion confusion to some, and in interpreting the results one should keep in mind these factors: Fairly frequently a negative reaction will result in a bird that is definitely tuberculous, and conversely, a positive result is sometimes obtained in chickens in which signs of tuberculosis cannot be demonstrated. In the latter instance, failure to find lesions of tuberculosis does not imply necessarily that tubercle bacilli are not present in the tissues of the chicken. If the disease is in an early stage, lesions are likely to be too small to be noted grossly or too few to be found by the ordinary methods of examination. In a satisfactorily large number of instances a definitely posi-
FIG. 12.5 — Cross sections of wattles. (a) Uninjected wattle showing the central connective tissue stroma and the epidermis of the opposite surfaces. tive tuberculin test in chickens indicates that the bird has been exposed to avian tubercle bacilli. If a sufficiently diligent search is made by methods that are proper and adequate, the infective bacteria can usually be demonstrated in positive reactors.

Tuberculin is a bacteria-free substance prepared from the metabolic products of tubercle bacilli and, as used for the diagnosis of tuberculosis in chickens, may be considered entirely harmless to tuberculous as well as to normal birds. Frequently the question is raised whether or not tuberculin injected into nontuberculous fowl may be responsible for a positive reaction on repetition of the test in the same bird. If retests are done after an interval of one month, false positive reactions will not occur. In other words, in chickens the usual diagnostic dose of tuberculin does not sensitize the nontuberculous animal to subsequent injections of the same product.[23]

The tuberculin test has been utilized to a limited extent in diagnosing tuberculosis of turkeys. However, for the most part the results have been less satisfactory than for chickens. Certain difficulties are encountered also in tuberculin testing of pigeons and ducks. Generally speaking, the test is of limited value in diagnosing tuberculosis in these animals.

Rapid agglutination test. A serologic procedure of possible diagnostic usefulness in tuberculosis of chickens was suggested by the report of Moses et al. (1943). The procedure was modified and its practical application demonstrated later by Karlson et al. (1950).

The principal modification introduced was the use of whole blood rather than blood serum. The essentials of the method for conducting the test at the present time are as follows:

(1) Selection of a suitable strain of avian tubercle bacilli for preparation of the antigen. The strain should be one that will produce a uniform and stable suspension. Obviously those strains that auto-agglutinate are not acceptable, and it may be necessary to examine many antigens before one obtained from a suitable culture is found.

(2) Blood for the tests is obtained by pricking the comb with a sharp instrument,

[23] Those interested in the relative value of modifications of the tuberculin test as applied to the wattles of chickens may consult Unruh (1959).
FIG. 12.6 — Results of four tests from four different chickens, two of which were tuberculous and two of which were not.

The two preparations illustrated in the upper row show characteristic agglutination. The blood was obtained from chickens that had reacted positively to tuberculin, and lesions of tuberculosis were found at necropsy. Preparations shown in the lower row failed to agglutinate. The negative reactions agreed with the results of tuberculin tests, and at necropsy lesions were not found. (From Karlson et al., 1950. Reproduction by permission of the American Journal of Veterinary Research.)

such as the point of an 18-gauge hypodermic needle. A drop of the blood is mixed on a warm plate with one drop of the antigen. The plate is kept warm and results are recorded in one minute. The appearance of negative and positive results is shown in Figure 12.6.

Limited observations indicate that the whole-blood agglutination test has a diagnostic reliability in chickens comparable to the tuberculin test. This test should be a relatively rapid and satisfactory procedure for detecting infected flocks. The procedure should be subjected to more extensive trials since it offers certain practical advantages. The animals need to be handled only once, and in addition, samples of blood submitted for agglutination tests for pullorum disease may also be examined for the presence of specific mycobacterial agglutinins.[24]

[24] The reliability of the rapid agglutination test as a diagnostic procedure for the detection of tuberculosis in turkeys should be explored.

PATHOLOGIC ANATOMY

If a proper understanding of the disease problem as it affects the chicken flock is to be obtained, it is essential that a careful necropsy be made of all birds that die. Such an examination, if conducted by one who has expert knowledge of disease, will supply information that can be secured in no other way and will reveal the cause of death in a large percentage of instances. This is especially true in tuberculosis, in which the morphologic signs of the disease are fairly characteristic.

The gross morbid changes associated with tuberculosis of chickens that have died of the disease are usually strikingly evident. If the bird has died suddenly, one frequently finds the abdomen filled with blood. The liver or spleen or both of these organs are greatly enlarged, and the source of the blood can be traced to rupture of one of these organs. Since birds suffering from leukosis may die as a consequence of rupture of the spleen or liver, additional evidence of tuberculosis must be sought in instances in which death was due to a fatal abdominal hemorrhage.

The pathologic changes in avian tuberculosis are those of an infectious granuloma, and although the lesions have a general similarity to those of tuberculosis in mammals, there are certain characteristic distinctions.

It should be kept in mind that the character of the reaction of the tissues to the tubercle bacillus is not determined entirely by the character of the organism, but also by certain indefinite factors which are inherent in the species harboring the infection.

Anatomic distribution of the lesions. Since in the majority of instances tuberculosis of chickens is initiated by way of the digestive tract, it is not surprising that organs other than the lungs should show the greatest incidence of involvement. Lesions of the disease are seen most frequently in the liver, spleen, intestines, and bone marrow. The tuberculous bacillemia, which probably occurs intermittently and perhaps early in most if not all instances
FIG. 12.7 — Tuberculous lesions in the liver of a naturally infected chicken.

FIG. 12.8 — Spleens from chickens naturally infected with tuberculosis. Note the variation in the number and size of the lesions.
FIG. 12.9 — Large nodulated lesions of tuberculosis in the wall of the small intestine of a chicken.

of tuberculous infection of chickens, provides a favorable circumstance for a widespread or generalized distribution of lesions. None of the tissues, with the possible exception of those of the central nervous system, appear to be immune from possible infection. Some of the organs, such as the heart, ovary, testes, and skin, are affected infrequently and cannot be considered organs of predilection. In one series of 100 necropsies I found the lungs to be affected either grossly or microscopically in 48 per cent.

Gross anatomy of the lesions. Grossly, avian tuberculosis is characterized by the occurrence of irregular grayish-yellow or grayish-white nodules of varying sizes in the organs of predilection such as the liver, spleen, intestine, and bone marrow (Figs. 12.7, 12.8, and 12.9). Involvement of the liver and spleen results in hypertrophy which is often of marked proportions. The tuberculous nodule, as observed grossly, varies in size from a structure that is just discernible to a huge mass that may measure several centimeters in diameter.[25] Nodules of large size frequently have an irregular knobby contour, with smaller granulations or nodules often present over the surface. Lesions near the surface in such organs as the liver and spleen are enucleated easily from the adjacent tissues. The nodules are firm but are incised easily since mineral salts are not present. On cross section there may be observed a fibrous nodule containing a variable number of small yellowish foci or a single soft, yellowish central region which is frequently caseous. The latter is surrounded by a fibrous capsule, the continuity of which often is interrupted by small circumscribed necrotic foci. The fibrous capsule varies in thickness and consistency depending upon the size and duration of the lesions. It is barely discernible or apparently absent in the smaller lesions and measures from 0.1 to 0.2 cm. in thickness in the larger nodules.

The number of lesions present is also variable, ranging from a few to innumerable. Large numbers of small lesions are particularly frequent in the liver and in the mesentery. It is fairly common to observe a few nodular lesions in organs such as the liver and spleen associated with an enormous number of lesions of minute to moderate size. The variation in size of such lesions is a consequence of successive episodes of reinfection from previously established lesions, usually of the same organ. Involvement of the lung is usually less severe than that of the liver or spleen (Fig 12.10).

The continuous progressiveness of tuberculosis of chickens, once the disease is established, and the marked tendency of the disease to disseminate to several organs of the body indicate, as mentioned previously, that tuberculous bacillemia is a common manifestation of the disease. That the blood stream of tuberculous fowl does contain virulent tubercle bacilli at times has been demonstrated repeatedly. This tendency of the bacilli to invade, and circulate with the blood stream provides the explanation for the frequent involvement of the bone marrow of tuberculous fowl (Figs. 12.11 and 12.12). Infection of the bone marrow probably occurs very early in the course of the disease and is characterized by hypertrophy of the myeloid tissues, by disappearance of most of the bony spicules, and finally by the formation in the marrow of tuberculous nodules. The latter may be numerous and strikingly evident to the unaided eye, or the lesions may be few and of such size as to require the use of the microscope for their demonstration.

Blood. Reliable data on the effects of a natural tuberculous infection on the circulating blood of chickens are somewhat meager. Some workers have reported anemia associated with a reduction in the total number of erythrocytes. Other observations have indicated that there occurs a marked increase in the number of large lymphocytes and a decrease in the small

[25] Detailed descriptions of the gross and microscopic lesions of tuberculosis in the different organs of chickens will be found in Feldman's (1938) monograph on avian tuberculosis infections.

FIG. 12.10 — Massive tuberculous involvement of one lung of a naturally infected chicken.

FIG. 12.11 — Several femurs and one tibio from chickens naturally infected with tuberculosis showing lesions in the myeloid tissue and some well-marked osteoplastic changes due to the infection.
FIG. 12.12 — Small tuberculous nodule in the bone marrow of a naturally infected chicken. The central necrotic region is surrounded by a zone of dense connective tissue. ×100.
FIG. 12.13 — Young epithelioid tubercle in the lung of a chicken. ×440.

lymphocytes. The work of Olson and Feldman (1936) on a relatively small number of naturally infected chickens indicated that the erythrocyte and thrombocyte counts and the values for hemoglobin were within the limits of normal. Although in our material the disease was presumably of long duration, anemia was not observed. Leukocytosis was the most striking and consistent finding, the number of monocytes and heterophils being increased. The degree of leukocytosis was for the most part in direct ratio to the extent and severity of the disease.

Histopathology of the tubercle. The anatomic unit of tuberculosis as the disease occurs spontaneously is conveniently designated a tubercle. The term "tubercle" as it refers to tuberculosis of fowl designates a structure which varies in character depending on its age and size. In its simplest form, which may be observed experimentally in 10 to 14 days after infection, there occurs a closely packed, microscopic collection of rather pale-staining cells with vesiculated nuclei. These cells, which have been designated as epithelioid cells, contain tubercle bacilli and are derived from fixed tissue elements known as histiocytes (Fig. 12.13). The latter cells have a marked attraction for tubercle bacilli, which they phagocytose early in the reactive process.

The cellular mass, or primary tubercle, gradually expands as a consequence of the proliferative activity of histiocytes at the periphery, and within three to four weeks after the tubercle first becomes demonstrable, signs of retrogression can be detected in the epithelioid cells of the central zone. This retrogression is due in part to the avascularity of the structure and in part to the toxic substances of the tubercle bacilli. As the cellular mass becomes larger, the epithelioid cells have a tendency to fuse and form syncytia. The outlines of individual cells become less distinct or disappear. Vacuoles appear, and the staining reaction is more acidophilic. This is followed within a week or so by a necrobiotic change resembling coagulation necrosis. The nuclei of the epithelioid cells become pyknotic and may disappear, while the cellular mass, excepting the peripheral portion, becomes fused and stains deeply with eosin. The tubercle bacilli have multiplied and appear singly or in clumps throughout the necrotic tissue. This completes the first phase in the evolution of the tubercle.

The second phase of the development of the tubercle is concerned with the formation of giant cells. While the epithelioid cells in the central zone undergo necrobiotic changes, there persists an outer zone of epithelioid syncytia which appears as a mantle around the entire periphery. From these, giant cells are developed. The giant cells thus formed may contain one or several nuclei. Infrequently, forms similar to Langhans' giant cells of mammalian tuberculosis may occur. The nuclei of the giant cells are situated distally to the central zone of necrosis, and the cells are arranged rather frequently in palisade formation. Large vacuoles often occur in the cytoplasm of the giant cells, and the nuclei stain intensely with the basic dyes. Immediately peripheral to the zone of giant cells there occurs a more or less diffuse collection of epithelioid cells and their progenitors, histiocytes (Fig. 12.14). Fibrocytes and minute blood vascular channels also occur near the outer portion of the peripheral area. Although tubercle bacilli are more numerous in the central or necrotic zone of the tubercle, they also occur in large numbers in the epithelioid zone, adjacent and distal to the giant cells.

The third and final phase in the formation of a tubercle is the development of a zone of encapsulation consisting of fibrous connective tissue, histiocytes, some lymphocytes, and an occasional eosinophilic granulocyte. In limiting the progress of the disease the encapsulating structure is usually inadequate owing to the continuous development of new tubercles in the epithelioid zone immediately peripheral to the giant cells. As a consequence of these new or so called daughter tubercles, a tubercle as recognized grossly consists of the original or parent tubercle and several

×120.

smaller or adjacent ones, which considered together form a conglomerate tubercle (Fig. 12.15).

In summary, it is convenient to consider that the adult tubercle as it occurs in chickens consists of four parts or zones. The first is the necrotic or central zone, and the second, the surrounding zone of giant cells. The third zone is that immediately peripheral to the giant cells and is composed of epithelioid cells and histiocytes. The fourth zone, which is not always apparent, is made up of histiocytes, small blood channels, and fibrous connective tissue elements.

The nature of the degenerative process which occurs in the central zone of the tubercle is somewhat unusual in that the integrity of the cells is maintained for a considerable period before disintegration becomes apparent. Caseation necrosis eventually occurs and may affect all or a part of the central zone. Caseation probably is engendered by the influx of leukocytes, and there results a more or less structureless mass composed of tissue debris and nuclear fragments among which tubercle bacilli are numerous.

By appropriate stains, lipid substances in variable amounts can be demonstrated in the lesions. The fat, which occurs in the form of small to moderately large globules, is most abundant in the more adult tubercles and of minimal amount in the prenecrotic epithelioid lesions.

In the first or epithelioid phase of the development of the tubercle, one can demonstrate by appropriate staining methods the presence of delicate reticulum fibrils which intertwine promiscuously among the epithelioid cells. When degeneration and necrosis occur, the reticulum fibrils no longer can be seen.

Calcification of the tubercle occurs rarely if ever, the failure of mineral salts to accumulate being one of the unique characteristics of the tuberculous lesion as it occurs in fowl. Amyloidlike degeneration of portions of the surrounding parenchymal elements sometimes is observed in the liver, spleen, and kidney.

The number of tubercle bacilli present in the lesions is much significance in the pathogenesis of avian tuberculosis. The propensity of the organism for growth and multiplication is hindered little if any within the tissues of chickens, and the result is prodigious numbers of bacilli in every lesion (Fig. 12.16). In this regard tuberculosis of chickens resembles two other mycobacterial diseases—leprosy and paratuberculosis. The organisms are exceedingly numerous in smears from the morbid tissues, and cultures of tuberculous tissue from chickens usually yield innumerable colonies of tubercle bacilli. The presence of tubercle bacilli in such large numbers within the tissues of a tuberculous fowl constitutes an important factor in the transmission of the disease to healthy animals and makes imperative the proper disposal of the carcasses of birds affected with tuberculosis.

Generally speaking, the morbid anatomy of tuberculosis of chickens is that of a serious, destructive, aggressive, granulomatous disease that seldom if ever heals spontaneously and, in the great majority of instances, will result directly or indirectly in the death of the affected fowl.

DISSEMINATION AND TRANSMISSION

Although several factors may contribute to the transmission and dissemination of avian tuberculosis to uninfected hosts, an infected environment is the element of first importance in the perpetuation of the disease. Should a high percentage of infection occur as a consequence of an infected environment, several related factors are of significance. These include: (1) the age of the chicken, adult chickens being more resistant than younger ones; (2) the concentration of the infective material, premises occupied by many tuberculous fowl over a period of years being a more potent source of infection than premises that have been contaminated recently by relatively few tuberculous fowl; (3) repeated episodes of exposure over a considerable period; and (4) the complex and little-understood question of individual
FIG. 12.16 – Numerous tubercle bacilli in a smear preparation from a small lesion of the lung of a naturally infected chicken (stained by the method of Ziehl-Neelsen). ×1,600.

susceptibility or resistance.

Of primary importance in the establishment of an infected environment are certain distinctive factors characteristic of the pathology of avian tuberculosis in the natural host. As mentioned before, the tremendous number of tubercle bacilli exuded from the frequently occurring ulcerated tuberculous lesions of the intestine establish the infected bowel as a constant source of virulent bacteria. These mix with the intestinal contents and eventually leave the body with the feces. Although other potential sources of infection exist, there is none that equals infective fecal material in the dissemination of avian tuberculosis from affected to nontuberculous animals. Related to enteric ulcerations as sources of tubercle bacilli that may occur in the fecal discharges are lesions of the liver and of the mucosa of the gallbladder. From such lesions the organism fairly commonly finds its way into the intestine through the common duct.

Egress of the bacteria from the respiratory tract is also a potential source of infection, especially if lesions occur in the tracheal mucosa in addition to the lungs. The ingestion of its infective exudates by a bird that has tuberculosis of the respiratory tract also provides a potent means of auto-infection, with lesions in the other organs, especially the intestines.

Vectors. The possibility that living foreign-host carriers may transport avian tubercle bacilli from infected to noninfected premises constitutes an interesting phase of the epidemiologic aspect of avian tuberculosis. Many have studied the problem, the report of Schalk et al. (1935) being especially noteworthy. Although a résumé of the facts indicates quite definitely that vectors have a role in the dissemination of avian tubercle bacilli from infected to healthy flocks, it is hardly likely that vectors are responsible for any considerable amount of the tuberculous infection that exists in the average farm flock. They are perhaps more important as possible sources of new foci of infection in premises that were previously free of the disease. The infective environment,

comprising as it does the bacilli-laden soil, litter, and filth, is the factor of greatest importance in the transmission of the disease to noninfected animals. The longer the premises have been occupied by infected birds and the more concentrated the poultry population, the more prevalent the infection is likely to be.

Role of eggs. The possibility that avian tuberculosis might be transmitted through the eggs from tuberculous hens has been a pertinent question since Sibley (1890) observed the occurrence of tuberculosis in chickens that had been hatched from eggs laid by hens affected with the disease. In attempting to explain the origin and continuation of the disease, Sibley stated that "the disease appears to be a clear case of heredity."

Generally speaking, the problem concerning the possible transmission of avian tuberculosis through infected eggs has been approached in two ways: (1) by inoculating eggs artificially with tubercle bacilli and noting whether or not tuberculosis eventually develops in the birds hatched from the infected eggs and (2) by observing whether or not tuberculosis develops in chickens hatched from eggs obtained from naturally infected hens.[26] It has been demonstrated many times that some of the eggs artificially inoculated with avian tubercle bacilli will hatch and that there is a good possibility that the chicks hatched from such eggs will be infected with tubercle bacilli. Furthermore, such infected chicks usually will die within a short time of extensive tuberculosis. Therefore, from a practical point of view, such observations are of doubtful importance to the fundamental question: Are eggs from naturally infected chickens likely to produce chicks that are destined to be tuberculous? Although the possibility that this might occur is admitted, there is at the present time no convincing experimental evidence to justify the conclusion

that chicks hatched from eggs laid by tuberculous hens will be infected with tubercle bacilli as a consequence of the infectious agent having been implanted in the developing embryo.

The most convincing evidence that infection from a tuberculous maternal parent is not likely to occur is that furnished by the investigations of Schalk et al. (1935) and Fitch and Lubbehusen (1928), who reared many hundreds of chicks hatched from eggs of naturally infected hens without tuberculosis having been observed in a single instance.

Other sources. Other potent sources of dissemination of avian tubercle bacilli are the carcasses of tuberculous fowl that die of the disease and the offal from chickens that, although tuberculous, are dressed for food. It is obvious that any tissue likely to contain living avian tubercle bacilli should be disposed of in such a manner as to preclude its being eaten by chickens or swine. Infected tissues preferably should be burned, or if the food value of such flesh be of sufficient importance, it should be cooked thoroughly before being used as food for animals.

It is also conceivable that cannibalism might play a part in the transmission of tuberculosis from one chicken to another. Since bacillemia is of frequent occurrence in the natural course of tuberculosis of chickens it is reasonable to believe that the fierce and bloody assault on an infected bird by one addicted to cannibalism would provide a possibility that the aggressor would ingest tubercle bacilli with the blood of the infected victim. Whether or not such exposure would be sufficient to produce tuberculosis is problematic.

Avian tubercle bacilli may be transmitted from one situation to another by persons whose shoes have become soiled with fecal matter and other filth of the poultry yard. The equipment used in the care and maintenance of infected poultry flocks, such as crates and feed sacks, also might be responsible for the transfer of the infective bacteria from diseased to healthy flocks.

---

[26] Fitch et al. (1924), as a result of a comprehensive study, concluded that viable tubercle bacilli are present in less than 1 per cent of eggs from tuberculous chickens

TUBERCULOSIS IN TURKEYS[27]

Turkeys are not uncommonly affected with tuberculosis, and the disease in most instances is contracted from infected chickens. The disease is chronic in character. Affected birds may occasionally be lame or emaciated. However, such signs are not pathognomonic. Definitive diagnosis is best established as a result of necropsy procedures.

Important information regarding tuberculosis in turkeys has been contributed by Hinshaw et al. (1932), who examined at necropsy a total of 88 birds; tuberculosis was found in 45, or 51.14 per cent. The incidence of the disease in relation to different age groups is of interest. The disease was found in only one of 11 birds less than one year of age. Of 24 between one and two years of age, 14 were tuberculous, whereas of 43 more than two years of age, 28, or 65.12 per cent, were tuberculous. In two instances the age of the birds was not known. These workers recorded the frequency of involvement of the different organs as follows: liver, 95.6 per cent; spleen, 67.3 per cent; intestine, 45.6 per cent; lungs, 32.6 per cent; ovaries, 32.2 per cent; thymus, 29 per cent; testes, 25 per cent; mesentery, 21.7 per cent; pancreas, 12.9 per cent; muscle, 11.7 per cent;[28] bones, 7.4 per cent; skin, 6.2 per cent;[29] gizzard, 5.7 per cent; esophagus, 4.7 per cent; pericardium, 4.5 per cent; proventriculus, 3.7 per cent; kidneys, 3.5 per cent; oviduct, 3 per cent; and myocardium, 2.2 per cent.

Microscopically, lesions of tuberculosis in the turkey vary considerably in their appearance. In some, tubercles essentially like those seen in tuberculosis of chickens are present. In other instances, the lesions are of a diffuse character with extensive destruction of the surrounding parenchymal tissues. Cytoplasmic masses, or large giant cells, may be numerous, and large numbers of eosinophilic granulocytes are commonly present. Some of the lesions become circumscribed by a broad, dense zone of fibrous connective tissue. At the periphery of such encapsulations, extensive infiltrations of lymphocytes are usually present.

As mentioned previously, the diagnosis of tuberculosis in turkeys is best accomplished by recognizing the lesions at necropsy. However, proof of the true nature of the infection is dependent upon subsequent laboratory studies designed to reveal the acid-fast characteristic of the etiologic agent and to establish the microorganism definitely as Mycobacterium avium. Conditions that may simulate tuberculosis and which must be excluded are mycosis, enterohepatitis, and certain forms of neoplasia.

From available information it appears that the usefulness of the tuberculin test in the diagnosis of tuberculosis in turkeys has not been adequately established. Hinshaw et al. (1932) using avian tuberculin, injected the snood, the mucosa of the anus, the wattle, the skin of the edge of the wing web, and the skin at the center of the wing web. The results of the tests indicated that (1) the reactions in the wattle agreed with the findings at necropsy in only 11.1 per cent of the birds, and (2) there was agreement between the tuberculin reaction in the wing web and the findings at necropsy in 75.68 per cent of the animals. Durant (1936) also found the skin of the wing web to be the site of choice for tuberculin testing of turkeys. From the meager information available, one must conclude that the intradermic tuberculin test has been less reliable for detecting tuberculosis in turkeys than in chickens. It would seem desirable to investigate the reliability of the rapid agglutination test as

---

[27] Information pertaining to tuberculosis in turkeys has been contributed by Eber (1924, 1925), Klimmer (1930), Proscholdt (1932), Sustmann (1917), Hinshaw et al. (1932), and Hinshaw, Chapter 41 of this book.

[28] The lesions designated as involving muscle were, according to Hinshaw et al. (1932) actually in the fascia.

[29] Instances of tuberculosis of the skin and of the subcutaneous tissues of turkeys have been described by Scrivner and Elder (1931), Chrétien et al (1923), and Dietrich (1927).

a means of detecting tuberculosis in live turkeys.[30]

Recommendations for the control of tuberculosis in turkeys include the following: (1) Rear and maintain birds so as to prevent contact with tuberculous chickens; premises and housing previously used by tuberculous chickens are to be avoided. (2) When tuberculosis is discovered in a flock of turkeys, the entire flock should be disposed of. (3) If a flock is to be re-established, the new stock should be limited to day-old poults.

CONTROL OF AVIAN TUBERCULOSIS

The eradication of avian tuberculosis or even its satisfactory control is not a simple matter. However, the widespread distribution of the disease, its high incidence in the more seriously infected areas, and the increasing importance of the poultry and the swine industries make it imperative that adequate measures be devised for its control and ultimate eradication.

As in most other infectious diseases, vaccination for the prevention of avian tuberculosis has been considered and tried. The products used include the so-called Friedmann vaccine,[31] an avian strain of BCG, and heat-killed avian tubercle bacilli. The result obtained from any of these products would not justify the claim that avian tuberculosis as the disease occurs naturally can be controlled successfully by vaccination. A measure of resistance can be conferred by the use of homologous strains, but much additional work will be necessary before vaccination can be accepted as worthy of serious consideration in the prevention of the disease.[32]

The tuberculin test if used judiciously is of considerable practical value in reducing the losses from tuberculosis. The subsequent removal from the flock of

chickens that react eliminates many foci of infection. The test enables one to detect many infected fowl before the disease reaches a severe or chronic state, and if repeated tests are made, potential dissemination of the infective bacteria to the surrounding environment may be reduced appreciably. However, this method if depended on alone for combating avian tuberculosis has many shortcomings, the most important being that if the residual flock is permitted to occupy the same infective premises a continuing source of infection remains. This provides opportunity for new infections to occur for an indefinite period since in the soil avian tubercle bacilli may remain viable and virulent for years. For this reason an environment once infected remains a potential source of infection indefinitely. Furthermore, neither the tuberculin test nor any other means can be depended on with absolute certainty to detect every living tuberculous fowl, and as long as one infected bird remains in a flock, dissemination of the disease to healthy fowl is possible. Consequently, means other than the tuberculin test must be resorted to if a more satisfactory control of avian tuberculosis is to be expected.

For the past several years it has been frequently stated that avian tuberculosis can be controlled if all birds in the flock are disposed of after the first laying season. This practice has much to commend it, especially since it is economically sound from the point of view of egg production. Older birds usually produce fewer eggs than the younger ones, and furthermore, the mortality from nonbacterial diseases such as neoplasia is greater among the older hens than among pullets. Another factor in favor of the disposal of the older stock is that if tuberculosis is present it is usually more severe in the older birds, which are as a consequence more likely to become depots of dissemination.

Desirable as it may be to dispose of the older birds, to maintain that this practice alone will rid the flock of tuberculosis

[30] Referred to previously (page 389) as a diagnostic test for tuberculosis in chickens

[31] Prepared from a so-called turtle strain of acidfast bacilli (*Mycobacterium chelonei*).

[32] The question of vaccination against tuberculosis of chickens is reviewed in Feldman's (1938) monograph on avian tuberculosis infections.

is at best an optimistic wish. Contrary to the belief of some, acute generalized tuberculosis occasionally occurs in pullets. The lesions in such a bird contain enough tubercle bacilli to infect a dozen flocks, and if the carcass be eaten by its mates, the likelihood that several additional birds will become infected is evident. To reiterate, the threat of avian tuberculosis in potentially serious proportions remains just so long as a single infected bird is a member of the flock.

Since it has been adequately established that the continuation of tuberculosis in a flock is dependent on an infected environment, it would seem reasonable to believe that this fundamental fact should be utilized in any program devised for the control and elimination of the infection. Basically the question is one of hygiene. That every case of tuberculosis comes from another case is aphorismic. The disease is due to a well-known and definitely established cause, the tubercle bacillus, and this fact must not be lost sight of or ignored when measures to eliminate the infection are considered. To permit young birds to range at will over infected premises or to occupy quarters that were used previously to maintain tuberculous birds is to insure the continuation of the disease indefinitely.

Procedures for establishing and maintaining tuberculosis-free flocks should embrace the following: (1) Abandon the old equipment and establish other facilities on new soil that is known not to be contaminated with avian tubercle bacilli. Ordinarily it is impractical to render an infected environment satisfactorily safe by disinfection. (2) Provide proper fencing or other measures to prevent the unrestricted movement of the chickens, thus preventing exposure from previously infected premises. (3) Eliminate as soon as possible the old flock, burning the carcasses of birds that show lesions of tuberculosis. (4) Establish a new flock in the new environment from tuberculosis-free stock. (5) Eliminate from the swine herd all reactors to avian and to mammalian tuberculin. New breeding stock should likewise be tuberculosis-free. If the chickens in such a flock are prevented from having access to an infected environment and are protected against accidental exposure to tubercle bacilli, it is reasonable to believe that they will remain free from tuberculosis.

The measures just mentioned for the elimination of avian tuberculosis are not complicated and should be applicable to most American farms. The additional profits that will accrue from a tuberculosis-free flock maintained in a hygienic environment will in time compensate adequately for the initial expense and work necessary to establish the new flock and new facilities. Furthermore, the general health of the birds will be better, and diseases other than tuberculosis will be controlled more satisfactorily. The benefits will also be reflected in a decrease in tuberculosis in swine. The importance of avian tuberculosis in the infection of swine is such that if chickens were maintained entirely separate and apart from swine, the incidence of tuberculosis of swine due to $M.$ $avium$ would be reduced to a minimum.

Some may be tempted to try to control or eliminate avian tuberculosis from infected birds and mammals by the use of antituberculosis drugs which have been effective in the treatment of tuberculosis in man. Such practice cannot be recommended. The organism of avian tuberculosis is characteristically much more resistant to presently known chemical agents in $vivo$ than is the human tubercle bacillus. Furthermore, the tuberculosis infection in chickens is often a formidable, destructive process, with hematogenous dissemination frequently, if not always, present. The procurement of a chemical agent sufficiently potent to eliminate the infection without serious untoward results on the affected animal seems unlikely and visionary at the present time. One may again emphasize: tuberculosis of poultry is best combated by elimination from the premises of all natural hosts infected with $Mycobacterium$ $avium,$ and by strict adherence to basic principles of sanitation and hygiene.

Infectious Coryza and Avian Mycoplasmosis*

Infectious Coryza (Roup, Hemophilus gallinarum Infection)

Infectious coryza is the name applied to a respiratory disease of chickens caused by the bacterium *Hemophilus gallinarum*. The disease is characterized by nasal discharge, frequent swelling or edema of the face, and sneezing. *H. gallinarum* infection was rather common during the 1930's and early 1940's and then almost disappeared, apparently occurring only in some flocks in California. The decreased incidence of the disease was attributed to better methods of isolation rearing, to the practice of disposing of the laying flock at the end of the year, and to the failure of *H. gallinarum* to survive outside the bird. However, the incidence of the disease appears to have increased some in recent years. It still is a problem in California and "Infectious Coryza" was reported as

being diagnosed in a few flocks in several states in 1963 (Angstrom, 1963, and Henderson, 1963), although definite confirmation of pathogenic *H. gallinarum* infection apparently has only been reported in California (Page, 1962a) and in Delaware (Benton, 1963) in recent years. It is also present in Brazil (Bueno, 1950), in Puerto Rico (Rivera-Analya *et al.*, 1953), and in Israel (Bornstein and Samberg, 1954).

Etiology. As early as 1927 de Blieck in Holland and Beach in the United States believed that the disease then known as contagious catarrh was a distinct entity. Since the disease frequently complicated fowl pox, one of the first problems was to separate the two infections. This was first accomplished by de Blieck (1931, 1932), who reported on the isolation of a pathogenic organism from a disease which he was able to transmit to pox-immune birds. He called the organism *Bacillus haemoglobinophilus coryzae gallinarum*. Nelson (1932) reported from New Jersey on the isolation of a hemophilic organism from uncomplicated coryza in chickens. Later

[405]

FIG. 13.1 — Hemophilus gallinarum in film of nasal exudate. ×810.
Schalm and Beach (1934), Eliot and Lewis (1934), and Delaplane *et al.* (1934) confirmed previous reports by de Blieck. Eliot and Lewis (1934) proposed the name *Hemophilus gallinarum*, by which the organism is known today.

H. gallinarum is a Gram-negative, pleomorphic, nonmotile bacterium. It is catalase negative, reduces nitrates, and ferments several carbohydrates under appropriate conditions (Page, 1962a). This organism, found in the sinus exudate of the infected chicken, has bipolar staining characteristics (Fig. 13 1). In young cultures it occurs as a short coccoid rod, but after 24 to 48 hours many long forms are found. The organisms form tiny, dewdroplike colonies on the surface of a suitable medium. *H. gallinarum* is fastidious in its growth requirements. Schalm and Beach (1936a, 1936b) found that their strains required two factors — an X-factor (hemin) which resisted autoclaving and was present in the red blood cells, and a V-factor (DPN) which resisted boiling for 5 minutes but was destroyed by autoclaving and was found in both the serum and red cells. Serum from defibrinated blood contained both factors. However, Gregory (1943) noted that the X-factor (hemin) was not necessary, and in more refined studies Page (1962a) demonstrated that *H. galli-*

narum readily grew in media which contained no iron porphyrin (hemin) derived from blood. He further found that reduced DPN was essential for growth and could be supplied by adding enzymatically reduced DPN by feeder (nurse) cultures of *Staphylococcus epidermidis*, or by the addition of chicken or sheep serum.

Most workers have considered that an atmosphere containing added CO_2 was necessary to obtain optimum growth of *H. gallinarum*. However, Nelson (1933b) obtained good growth on blood agar plates which were sealed with clay, and Page (1962a) recently demonstrated that *H. gallinarum* was not dependent upon CO_2 as such, but was microaerophilic. He obtained good growth with reduced oxygen levels as well as under completely anaerobic conditions. Methods to obtain reduced oxygen levels include the addition of CO_2 to the incubation chamber or the removal of some of the oxygen by burning out a candle in a sealed container.

Early workers devised a number of different media which supported the growth of *H. gallinarum*, due primarily to ingredients which supplied the necessary V-factor (DPN) although a source of the X-factor (hemin) was frequently included.

Nelson (1932, 1933a) and Delaplane *et al.* (1936) used blood at the base of agar

slants. Delaplane and Stuart (1939) found a growing yeast medium to be satisfactory. Cunningham and Stuart (1944) found an egg yolk medium suitable for growth of *H. gallinarum*. Gregory (1943) described a superior medium in which pieces of raw potato were used in chicken infusion broth. He emphasized the necessity of using salt in the medium. Hofstad (1959) used chicken infusion agar into which was incorporated 10 per cent chicken serum before slanting the agar. The organism colonized on the surface of the slant in a 10 per cent CO_2 atmosphere. This was a suitable medium for subculturing the organism after initial isolation on blood agar plates incubated in a partial atmosphere of CO_2. The use of blood agar plates incubated under a reduced oxygen tension appears to be a practical method for original isolation of *H. gallinarum*. Tryptose agar supplemented with a source of reduced DPN was found to be adequate by Page (1962a). Broth media are seldom employed for original isolation attempts because of the possibility of contaminant bacteria in respiratory tract exudates. However, Hofstad (1964) found that chicken meat infusion broth containing 3–5 per cent added chicken or turkey serum was valuable for subculturing *H. gallinarum* after original isolation. Page (1962a) obtained good growth when as little as 0.1 per cent chicken serum was added along with 1 per cent glucose to tryptose broth which had been filter sterilized after supporting the growth of *Staph. epidermidis*.

Another method for the propagation of *H. gallinarum* is the use of embryonated chicken eggs inoculated into either the yolk sac or the chorioallantoic sac. Infective yolk or allantoic fluid can then be harvested. Bacterial contaminants present in respiratory tract exudates limit the usefulness of this procedure for original isolation purposes.

H. gallinarum is an organism of low resistance outside the bird. De Blieck (1934) found it was killed after 24 hours at 37° C. when suspended in saline. The organism was dead when tested after 4 days at 22° C. Eliot and Lewis (1934) found it did not survive a temperature of 45° C. for 6 minutes when suspended in water. When suspended in hemolyzed blood broth, the organism was killed at 55° C. in 4 to 6 minutes, but survived 10 minutes at 50° C. Page (1962b) reported that the organisms in infectious nasal exudate suspended in tap water were viable for 3 but not 4 hours. Organisms which had been cultivated on agar medium and then suspended in tap water were nonviable within 4–12 minutes. *H. gallinarum* present on the legs of houseflies which had fed on infectious nasal exudate remained viable for only 15–30 minutes. Hofstad (1964) found the organism to survive for at least 10 years in the lyophilized state. The virulence of the organism for chickens is reduced by culturing on artificial media, and usually after 20 to 40 transfers the organism becomes avirulent. Recent reports by Page (1962a) and Page *et al.* (1963) indicate the existence of at least 2 serotypes of pathogenic *Hemophilus gallinarum*, although they were not found to be immunogenically distinct in cross protection studies. The 2 serotypes differed in their ability to ferment sucrose. He also described 3 nonpathogenic serotypes which were not typical of *H. gallinarum* (Page, 1962a). These organisms probably should only be designated as *Hemophilus* species at this time. They were strongly catalase positive, grew aerobically, required DPN (but not reduced DPN) for growth and some produced pigment in the presence of glucose.

Symptoms. In most cases of coryza there is involvement of the sinuses and nasal passages with a nasal discharge, swelling or edema of the face, conjunctivitis, and sneezing. Figure 13.2 illustrates the typical facial swelling. In males particularly there may be swollen wattles. Feed and water consumption by the affected flock usually is decreased, and in a laying flock this means fewer eggs, loss of weight, and increased number of culls. A foul odor may be detected in flocks where the disease has become chronic and complicated with

FIG. 13.2 — Artificial infection with infectious coryza showing facial edema.

other bacteria. Beach and Schalm (1936) and Delaplane and Stuart (1941a) have observed that *H gallinarum* infection also may involve the trachea and bronchi, causing rales and difficult breathing.

Transmission and incubation period. Infectious coryza most often occurs in the fall and winter. Outbreaks frequently are started by introducing carriers into the flock. Pullets may acquire the disease from recovered birds kept over from the previous year. Infection within the flock is spread by contact and by air-borne infected dust or droplets. The disease may spread rapidly through the flock, or transmission may take place more slowly depending, apparently, upon virulence of the organism and other factors. Page (1962b) concluded that the primary medium for intraflock transmission of infectious coryza was drinking water contaminated with infective nasal exudate. Intraflock transmission due to aerosol exposure appeared to be slower and less extensive in his studies. Transmission by caretakers and houseflies could not be demonstrated.

The incubation period after experimental inoculation is 18 to 36 hours. Susceptible birds exposed by contact to infected cases usually have symptoms of the disease in 1 to 3 days.

Course and mortality. The duration of infectious coryza is variable, but usually the disease persists through the cold months of the year if permitted to run its course. Complicating factors, such as secondary bacterial invaders, poor housing, parasitism, and inadequate nutrition, may add to the severity and duration of the disease. Nelson (1933b) has recorded a duration of 4 to 18 days in experimental cases produced by infected exudate. During the summer months infectious coryza may be less severe with a shorter duration. The virulence of various strains of the organism may alter the course of the disease. Delaplane *et al.* (1933) described a severe disease with high mortality in their original report on infectious coryza in Rhode Island. Schalm and Beach (1936a, 1936b) observed increased virulence by rapid passage of some strains in susceptible chicks and noted a difference in virulence on poultry farms.

Pathology. *H. gallinarum* produces an acute catarrhal inflammation of the mucous membranes of the nasal passages and sinuses. Airsacculitis was noted by Page (1962a,b). There is frequently a catarrhal conjunctivitis and a subcutaneous edema of the face and wattles. A chronic inflammatory process accompanied by caseous exudate in the sinuses, nasal passages, and conjunctival sacs is present in cases of long standing when the disease is complicated with other bacteria.

Diagnosis. A field diagnosis of *H. gallinarum* infection is difficult to make since other diseases, such as chronic cholera, fowl pox, A-avitaminosis, and the "chronic respiratory disease," may produce similar clinical symptoms. A method of making a field diagnosis was suggested by Delaplane and Stuart (1941b) and by Wernicoff and Goldhaft (1944). It consisted of treating the affected flock with sulfathiazole and observing the response. A diagnosis of *H. gallinarum* infection could be made if the flock responded favorably to the treatment within a week.

In the diagnostic laboratory it is desirable to inoculate susceptible chicks with suspected field material in order to de-

termine the transmissibility and the incubation period. If the inoculated chicks develop a nasal discharge and facial swelling within a few days, *H. gallinarum* infection may be suspected and attempts should be made to culture the organism, which may be found most consistently in the infraorbital sinus exudate. Isolation of an organism with characteristics of *H. gallinarum* and which will produce symptoms of coryza in chickens within a few days constitutes a diagnosis of infectious coryza.

Page (1962a) employed plate agglutination with hyperimmune chicken sera in his serological studies. It is possible that such a procedure might be employed with sera from convalescing birds to aid in making a laboratory diagnosis.

Treatment. Delaplane a n d Stuart (1941b) found sulfathiazole effective in reducing the severity of infectious coryza. Schlenker *et al.* (1941) found that concentrations of 3/16 gm., or greater, of sulfathiazole per ounce of mash established a blood level sufficient to prevent the development of symptoms of coryza after artificial exposure. Hamilton (1943) also found the drug to be effective in field outbreaks of the disease. Wernicoff and Goldhaft (1944) found sulfathiazole at the rate of ½ lb. per 100 lb. of dry mash to be effective in acute coryza. The above workers frequently noted a recurrence of the symptoms after the drug was withdrawn, thus indicating that it is necessary to continue or repeat the treatment. Improvement of the flock is usually observed within a week after treatment is begun. Streptomycin also has been found effective in treating infectious coryza (Bornstein and Samberg, 1954, 1955a, 1955b) at a dosage of 200 mg. intramuscularly. However, Page (1962b) found that his test isolate of *H. gallinarum* was relatively resistant to dihydrostreptomycin and sulfathiazole, but was reasonably sensitive to erythromycin and oxytetracycline. Intramuscular injections of erythromycin, oxytetracycline, and dihydrostreptomycin did not greatly alter the course of the disease in experimentally infected birds, though. Erythromycin given

for 4 days in the drinking water reduced the spread of infection among susceptible chickens, apparently due to its bactericidal effect in the water and in reducing the number of shedders, but following its removal a relapse in the flock was apparent. Modification of the feeding program to stimulate feed consumption may be desirable when birds are not eating. It is advisable to correct faulty ventilation or other factors contributing to the severity of the disease.

Eradication. The removal of recovered birds from the flock is necessary if the disease is to be eradicated from the premises, because recovered birds remain reservoirs of infection. The method of eradication depends upon circumstances on the farm —that is, size of flock, facilities, and purposes of the flock. The infected birds may be marketed at once and the premises cleaned before new chicks are brought on the place. Another more popular method is to treat the affected flock and keep it isolated until new stock has been raised in isolation as replacements. After the infected or recovered birds are marketed, the house should be cleaned and disinfected before housing the new stock.

Prevention. Because recovered birds are carriers and are responsible for new outbreaks, such practices as buying breeding males or started chicks should be discouraged. Only day-old chicks should be secured for replacement purposes unless the source is known to be free of infectious respiratory disease. Isolation rearing and housing away from old stock are desirable practices for the prevention of respiratory diseases.

A more recent approach to the prevention of infectious coryza consists of various "vaccination" procedures. Tennison and Siddle (1961) inoculated young chickens intramuscularly with live *H. gallinarum* of embryo origin. They reported reasonable protection when the birds were challenged 3–4 weeks later. However, live cultures should be employed judiciously if eventual eradication of the disease is contemplated. They also conducted trials

with a formalin inactivated bacterin which produced reasonable protection following 2 doses given 2 weeks apart. Clark and Godfrey (1961) used formalinized embryo fluids to prepare an oil emulsion type bacterin. They noted a decrease in the severity and duration of coryza in flocks which were naturally exposed to chickens with infectious coryza, CRD, and pasteurellosis.

Page et al. (1963) also studied the use of formalinized bacterins. They noted only limited resistance to upper respiratory infection, but did demonstrate some protection against the occurrence of airsacculitis and a resistance to a drop in egg production in laying chickens challenged with *H. gallinarum*. The effectiveness of bacterins under various field conditions needs further study, but undoubtedly will vary with the extent of exposure to natural infection and complicating conditions such as pasteurellosis, CRD, and other respiratory infections.

Avian Mycoplasmosis

(Mycoplasma gallisepticum infection, chronic respiratory disease)

Avian mycoplasmosis essentially is the disease caused by *Mycoplasma gallisepticum* infection, which frequently has been called chronic respiratory disease (CRD) of chickens and infectious sinusitis of turkeys. It is characterized by respiratory rales, coughing, and nasal discharge. The clinical manifestations are slow to develop and the disease has a long course. The disease has become an important flock problem in all areas of the United States. It is also present in Canada (Fahey *et al.*, 1953), Holland (de Blieck, 1950), Brazil (Garust and Nóbrega, 1956), the Philippines (Quizon, 1958), India (Pathak and Singh, 1961), Japan (Tajima *et al.*, 1958), England (Chu, 1958), Germany (Hartwigk, 1958), Switzerland (Keller, 1958), Egypt (Eissa, 1956), France (Brion *et al.*, 1958), Australia (Cottew, 1956), South Africa (Coles and Cumming, 1959) and Czechoslovakia (Striker and Fisera, 1955).

Etiology. Nelson (1936a-d, 1938, 1939) studied an agent, isolated from a coryza

of chickens, which he described as coccobacilliform bodies. He was able to grow them in tissue culture, embryonating chicken eggs, and in cell-free medium. Smith *et al.* (1948) studied Nelson's agent and found it grew well in ascitic peptic digest plates and in infusion broth enriched with 30 per cent horse serum. From cultural and morphological characteristics they concluded that Nelson's coccobacilliform bodies could be included in the pleuropneumonia group of organisms.

Delaplane and Stuart (1943) cultivated an agent in embryos isolated from chickens with a chronic respiratory disease, and later from turkeys with sinusitis (Delaplane, 1949). Markham and Wong (1952) placed the agent of chronic respiratory disease in the pleuropneumonia group. It appears likely that Nelson's agent was the same as the one later isolated by Delaplane. This is further supported by the finding of Adler and Yamamoto (1956b) that a combination of *Hemophilus gallinarum* and avian pleuropneumonialike organism

FIG. 13.3 — Giemsa's stained smear of sedimented broth culture of Mycoplasma gallisepticum, ×885.

(PPLO) resulted in a disease of rapid onset and long duration which Nelson produced with a combination of *H. gallinarum* and coccobacilliform bodies.

Edward and Kanarek (1960) proposed the name *Mycoplasma gallisepticum* for the typical pathogenic PPLO which causes chronic respiratory disease in chickens and infectious sinusitis of turkeys. The earlier named species *M. gallinarum* (Freundt, 1957) was found to represent a nonpathogenic serotype.

The organism is usually coccoid and about 0.5μ in size (Fig. 13.3). It has been studied by electron microscopy, and some variation in morphology has been found (Reagan *et al.*, 1953; White *et al.*, 1954). Some strains are spherical and others contain filaments (Fig. 13.4). Shifrine *et al.* (1962) studied the edge of growing colonies and concluded that the elementary cells were hexagonal and originated from within larger cells or by fragmentation of peripheral filaments. The organism stains well with Giemsa's stain and requires for its growth a medium enriched with serum or serum fraction. It is resistant to penicillin, polymyxin, neomycin (Wong and James, 1953), and low concentrations (1:4000) of thallous acetate. It can be grown on serum-enriched agar medium where it produces a characteristic colony with a dense, raised, central area (Fig. 13.5). Most strains of *M. gallisepticum* will cause agglutination of washed red blood cells of the chicken and turkey. Another
FIG. 13.4 — (Top left) Electron micrographs of M. gallisepticum Isolate 595. ×3,500. (Top right) Same. ×5,000. (Bottom left) Same. ×11,000. (Bottom right) Isolate 197. ×14,000. (Corr and Hofstad.)

characteristic of the organism is its ability to pass through filters which ordinarily retain bacteria. Using embryo-propagated material in the form of a suspension of the chorioallantoic membrane at a 1:100 dilution, the organism filters through the Selas 02, Berkefeld V and N, and Mandler 6 and 7 filters if sufficient amounts are filtered. It is withheld by the Berkefeld W, and the Seitz sterilizing pad. Organisms in broth culture readily pass through the Selas 02, but are partially retained by the 03 Selas filter.

Mycoplasma gallisepticum can be propagated in embryonating chicken eggs where it may or may not cause death of the embryo. Some strains, after a few passages, regularly cause mortality when inoculated into the yolk sac of seven-day-old embryonating chicken eggs (Hoyt *et al.*, 1951; Hofstad, 1952). On original isolation of some strains in embryos, there may be no mortality and no definite lesions, and it is necessary to make additional passages or to culture the embryo in suitable broth
FIG. 13.5 — Colonies of Mycoplasma gallisepticum on 20 per cent chicken serum agar plate. X40.

FIG. 13.6 — Joint involvement and stunting of 18-day-old chicken embryos inoculated with strain 640 of Mycoplasma E serotype at 7 days into the yolk sac.

in order to identify the organism. Some strains may produce caseous exudation in the respiratory tract of embryos (Van Roekel et al., 1952) but dwarfing, generalized edema, liver necrosis, and enlarged spleen in infected embryos dying between 14 and 21 days are most commonly observed (Chute and Cole, 1954).

Delaplane (1948) observed "joint abscesses" in infected embryos (Fig. 13.6) as did Van Roekel et al. (1957), Thompson (1954), Moulton and Adler (1957), Calnek and Levine (1957), and Chute (1960) who described the lesions as being primarily subcutaneous periarticular granulomas with necrotic centers and a border of epithelioid cells, some of which had coalesced to form giant cells. However, Yoder and Hofstad (1964a) concluded that such lesions were produced by Mycoplasma representing other serotypes than that of M. gallisepticum.

The organism reaches its highest concentration in the yolk sac and yolk and in the chorioallantoic membrane just prior to death of the embryo (Hofstad, 1952; Luginbuhl and Jungherr, 1953).

A number of media have been used for isolation and growth of M. gallisepticum (Markham and Wong, 1952; Grumbles et al., 1953; Adler and Yamamoto, 1956c; Hofstad and Doerr, 1956; Fabricant, 1959). All these have as enrichment either a concentrated serum fraction (Difco) or heat-inactivated horse, avian, or swine serum. Comparisons of different media have been made (Adler et al., 1954; Lecce and Sperling, 1954; Taylor et al., 1957; Taylor and Fabricant, 1957; Fabricant, 1958 and 1959; Adler and Berg, 1960). It is apparent that several types of liquid or agar media will support the growth of Mycoplasma of avian origin, but it is doubtful if any single medium is superior for the isolation of all possible Mycoplasma.

M. gallisepticum ferments dextrose and

maltose with the production of acid, but not gas. It does not ferment lactose. The fermentation of sucrose has been reported by several investigators (Grumbles et al., 1953; Granforte et al., 1955; Adler et al., 1958; Yamamoto and Adler, 1958b; and Kleckner, 1960). However, Yoder and Hofstad (1961a) were unable to demonstrate the fermentation of sucrose by any of the 29 isolates of M gallisepticum which they studied. Results with trehalose, mannitol, and galactose have also been variable

Granforte et al. (1955) studied seven isolates of avian Mycoplasma from different geographic areas and found these to be serologically identical and with similar hemagglutinating capacities. However, Adler et al (1957) differentiated at least 2 serotypes. Five serotypes were apparent as reported by Adler et al (1958) and were subsequently further characterized by Yamamoto and Adler (1958a, 1958b). Kleckner (1960) described 8 serotypes designated A through H. Serotype A was represented by M gallisepticum, which has frequently been designated as the S6 serotype (Zander, 1961) Yoder and Hofstad (1962) characterized another serotype. All of these reported serotypes were included in the 12 serotypes (A through L) which were recently characterized by Yoder and Hofstad (1961a) and in the 19 serotypes (A through S) characterized by Dierks (1963) Fabricant (1960), Fabricant and Levine (1962), and Kelton and Van Roekel (1963) employed the colony inhibition technique to differentiate various serotypes. They both noted that isolates representative of serotypes E and G were indistinguishable by the colony inhibition technique although separable by agglutination assays. Adler et al. (1961) described a saprophytic Mycoplasma obtained from chickens which was subsequently identified as M. laidlawii (Adler, 1964). Thus, there have been at least 20 serotypes of Mycoplasma found to be associated primarily with the respiratory tract of various avian species. However, Mycoplasma gallisepticum is of major significance as a pathogen for chickens.

M. gallisepticum is well preserved in lyo-

philized form and also in the frozen state. Infective turbinates suspended in tryptose phosphate broth have remained infective for five years stored at approximately −30° C. Yoder and Hofstad (1961a) found broth cultures to be viable after at least 4 years storage at −30°C. They also obtained viable M. gallisepticum from lyophilized chicken turbinate suspensions which had been stored at 4° C. for approximately 14 years. Fabricant (1953) recovered the organism from 60 per cent, 35 per cent, and 13 per cent of infective materials stored at −25°C. for one, two, and three years, respectively. Broth suspensions of infective chorioallantoic membranes lost their infectivity after 1 hour of exposure to 45° C., or after 20 minutes of exposure to 50° C. Similar material lost its infectivity by the third week in the refrigerator at 5° C. Olesiuk and Van Roekel (1952), however, found infective allantoic fluid to remain infective for 4 days in the incubator, for 6 days at room temperature, and 32 to 60 days in the refrigerator.

While M. gallisepticum is considered the primary cause of chronic respiratory disease, other organisms frequently cause complications, particularly in broilers (Baddle and Cover, 1957). Escherichia coli (especially O-group 2) has been found to be a frequent complicating organism in cases of air-sac infection in broilers (Wasserman et al., 1954; Gross, 1956; Glantz et al., 1962). Newcastle disease or infectious bronchitis infection may precipitate outbreaks of M. gallisepticum infection (Van Roekel et al., 1957). The effect of M. gallisepticum, E. coli and infectious bronchitis virus in singly and in multiply infected chickens was studied by Gross (1961a) and Fabricant and Levine (1962). They reproduced a severe air-sac infection, frequently designated complicated CRD or air-sac infection, when all 3 agents were combined. They further noted that E. coli could not readily infect the air sacs unless they were previously invaded by M. gallisepticum alone or in combination with either infectious bronchitis virus or (Gross, 1961b,

1962) Newcastle disease virus. Adler et al. (1962) and Blake (1962) noted increased severity and duration of the disease when both M. gallisepticum and infectious bronchitis virus were present. A virus isolated by Fahey and Crawley (1954a) from outbreaks of chronic respiratory disease has not been proved to have a significant role in the etiology of the disease.

It has been postulated by Kelton and Gentry (1957 and 1960) that the avian pleuropneumonialike organisms (PPLO) associated with chronic respiratory disease of chickens are L-forms of certain bacteria. This is based on the observation that PPLO broth cultures presumably revert primarily to staphylococci by the third transfer. However, conclusive proof that avian PPLO are actually L-forms of bacteria has not been published.

Transmission and incubation period. Outbreaks of the disease are often started by carriers, and the disease is spread by contact and by air-borne dust or droplets (Fahey and Crawley, 1955a). Van Roekel et al. (1952) found evidence that the disease may be transmitted through the egg. This has been confirmed by other investigators (Fahey and Crawley, 1954b; Cover and Waller, 1954; Hofstad, 1957a). The isolation of M. gallisepticum from the oviduct of infected hens and from the semen of infected roosters was reported by Yoder and Hofstad (1964a). Delaplane and Stuart (1943) and Van Roekel et al. (1952) found the incubation period to vary from 4 to 21 days in experimental transmission. Hofstad (1952) found that 65 per cent of 233 chicks had symptoms of nasal discharge between 11 and 18 days following intranasal inoculation of infective turbinate suspensions.

Susceptible hosts. The disease is common in chickens and turkeys. Guinea fowl and pheasants were readily infected with M. gallisepticum (Van Roekel and Olesiuk, 1953), and Osborn and Pomeroy (1958) isolated the agent from naturally infected pheasants. Pigeons and partridges were included as susceptible hosts by Jungherr et al. (1953). Natural infection in chukar

partridges (Alectoris graeca) has been reported by Wichmann (1957) and Yoder and Hofstad (1964a). The later workers were unable to produce infection in pigeons or Bobwhite quail (Corlinus virginianus) although previous reports suggested the infection had occurred in pigeons (Winterfield, 1953; Gianforte et al., 1955). Wills (1955) isolated the agent from an infected peacock (Pavo cristatus).

Symptoms. The most characteristic signs of the natural disease in adult flocks are tracheal rales, nasal discharge, and coughing. Feed consumption is reduced and the birds lose weight. In laying flocks egg production declines but is usually maintained at a lowered level. Male birds frequently have the most pronounced symptoms, and the disease is most severe in the winter. In broiler flocks most outbreaks occur between 4 and 8 weeks of age. The symptoms are frequently more marked than observed in mature flocks. The severe outbreaks observed in broilers are frequently due to complications (see Etiology.)

Course and mortality. The duration of M. gallisepticum infection is long, and the severity may vary considerably in different flocks. Inbred lines of chickens often have a more severe form of the disease with a longer duration than crossbred chickens. When the disease occurs during the summer in growing flocks, the birds usually recover more promptly than those which acquire the disease during the cold months of the year. Delaplane and Stuart (1943) observed the duration of experimental cases to vary from 21 to 68 days.

The mortality is negligible in adult flocks, but there may be considerable loss from lowered egg production and development of culls. In broilers, the mortality varies from very low in the uncomplicated disease to as much as 30 per cent in the complicated outbreaks. Retarded growth, grading down of carcasses, and condemnations constitute additional loss in broilers.

Pathology. The gross lesions consist primarily of catarrhal exudate in the nasal passages, trachea, bronchi, and air sacs.

FIG. 13.7 — lympho-follicular or "beading" reaction in air sac of experimentally inoculated turkey. (Van Roekel et al., Univ. of Mass.)

The air sacs frequently contain caseous exudate and may present a "beaded" appearance (Fig. 13.7). The tracheal mucosa is usually thickened. Some degree of pneumonia may be observed (Van Roekel et al., 1952).

The microscopic pathology has been studied by Jungherr et al. (1953) and by Van Roekel et al. (1957). They found marked thickening of the mucous membrane of the affected tissues due to infiltration with mononuclear cells and hyperplasia of the mucous glands. Focal areas of lymphoid hyperplasia (lympho follicular reaction) were commonly found in the submucosa (Figs. 13.8, 13.9, 13.10). Johnson (1954) regarded these as specific for chronic respiratory disease. Hitchner (1949) found them characteristic in his study of the pathology of infectious sinusitis of turkeys. However, Barber (1962) observed similar lesions in apparently normal turkeys, and suggested that the presence of lympho follicular lesions may be of limited diagnostic value. In the lungs, in addition to pneumonic areas and the lympho follicular changes, granulomatous lesions were also found. Van Roekel et al. (1957) found granulomatous lesions in lungs of about 22 per cent of field cases in chickens but in only 7 per cent of experimentally inoculated chickens.

Diagnosis. The diagnosis of $M.$ $gallisepticum$ infection should be based on isolation and identification of the organism. Suspensions of tracheal or air-sac exudate, turbinates, or lungs may be cultured directly in a suitable broth medium. Contamination may be controlled by a 1:4000 dilution of thallous acetate and up to 2,500 U. per ml. of penicillin. Contaminants may also be eliminated by filtering the suspension through a series of Selas filters beginning with the 01 and continuing through the 015 and then through the 02 filter. Both the 015 and the 02 filtrates should be cultured. The advantage of fil-
FIG. 13.8 — Section through nasal passages and sinuses of experimental chicken. Unilateral mucosae thickening of sinus and nasal passage. X6. (Van Roekel et al., Univ. of Mass.)

tration is that it eliminates tissue debris in the cultures, and the material is then suitable for embryo inoculation. The disadvantages are that it is time-consuming, and the possibility exists that small amounts of the organism may be adsorbed to the filter. Contaminants may also be controlled by first inoculating the material into the sinus of a turkey. Usually the sinus exudate that results is free of contaminants.

Cultures should be incubated several days to a week, and if tissue debris is present, the culture is shaken, allowed to settle a few minutes, and a transfer made to fresh medium. Growth may be detected grossly or an indicator system may be used, such as phenol red with maltose or triphenyltetrazolium chloride (Somerson and Morton, 1953). The latter is reduced by *M. gallisepticum*, changing the broth to pink or red, and has been found useful by Yoder and Hofstad (1964). Smears made from the sediment after centrifugation of cultures at 2,500 RPM for 15 minutes and stained with Giemsa's stain (2 ml. concentrated stain to 50 ml. water) should reveal small coccoid organisms, as shown in Fig-

FIG. 13.9 — Section of sinus in thicken. Subepithelial infiltration of mononuclear cells and lympho-follicular reaction. ×36. (Van Roekel et al., Univ. of Mass.)
FIG. 13.10 — Air sac of 7-week-old experimental chicken, lympho-follicular reaction. ×100. (Van Roekel et al., Univ. of Mass.)

ure 13.3. Frequently the organisms appear in large masses or clumps in the first few culture passages. Enriched agar medium may be inoculated from the broth culture to study the colonial morphology.

Further identification of *M. gallisepticum* can be made by preparing an antigen for an agglutination plate test with a known positive agglutinating serum. The antigen may also be used to prepare, in chickens, turkeys, or rabbits, an antiserum which is then tested against a known culture of *M. gallisepticum*. The hemagglutinating capacity of the isolate should be tested, and if positive, a hemagglutination-inhibition test may be set up with known positive serum. It is desirable to make a pathogenicity test either in the sinuses or air sacs of turkeys or in chickens. Evidence that the organism is pathogenic may be manifested if such an inoculation results in sinus swelling, air-sac exudate, and antibody response to a known antigen of *M. gallisepticum*. Histological sections would also aid in the diagnosis (see Pathology).

Serological procedures are available to aid in the diagnosis. However, since these tests are only evidence of recent or past infection, they cannot be relied upon solely for a diagnosis. A positive serological test, together with history and symptoms typical of the disease, would constitute a presumptive diagnosis.

Treatment. *M. gallisepticum* is susceptible to contact with certain antibiotics: streptomycin, oxytetracycline, chlortetracycline, erythromycin, magnamycin, spiramycin, and tylosin (Wong and James, 1953; Domermuth and Johnson, 1955; Yamamoto and Adler, 1956; Hamdy et al., 1957; Kiser et al., 1961; Yoder et al., 1961). However, some strains of *M. gallisepticum* have been reported to be rather resistant to streptomycin, erythromycin, and spiramycin (Fahey, 1957; Yoder et al., 1961; Domermuth, 1958, 1960; Kiser et al., 1961).

Various antibiotics and chemicals have been injected or administered in the feed or water for the treatment of chronic respiratory disease (Peterson, 1953; Carson et al., 1954; White-Stevens and Zeibel, 1954; Cover, 1955; Fahey and Crawley, 1955b; Lecce and Sperling. 1955; Adler et al., 1956; Barnes et al., 1960, 1961; Gross, 1961b; Heishman et al., 1960, 1962; Kiser et al., 1960; Olesiuk and Van Roekel, 1959; Olesiuk et al., 1957, 1964; Olson et al., 1959, 1960). The results of the various treatment studies have been variable, probably reflecting the varied complicating infections present in a wide spectrum of age groups under diverse conditions. In many cases it is doubtful if the small increase in weight gains or egg production and moderate reduction of carcass condemnations is sufficient to cover the cost of treatment. However, some of the more commonly employed treatments which tend to provide favorable results include the use of oxytetracycline or chlortetracycline at 200–400 grams per ton of feed for at least several days. Such broad spectrum antibiotics have been potentiated with approximately 0.5 per cent terephthalic acid and sometimes a reduced calcium ration. Tylosin has been injected subcutaneously at 3–5 mg. per pound of body weight or administered at 2–3 gm. per gallon of drinking water for 3–5 days. Antibiotic injections of infected breeding stock to control egg transmission have been widely used (see Control).

Immunity. Chickens which have recovered from clinical signs of the disease have some degree of immunity. Such flocks, however, carry the organism and can transmit the disease to susceptible stock by contact or can infect the progeny of the flock by way of the egg. (For immunization see Prevention and control.)

Serological procedures. Jungherr et al. (1953) first recognized the possibilities of certain serological procedures in *M. gallisepticum* infection. The rapid serum plate test was used by Adler (1954). Antigen is prepared according to the procedure of Adler and Yamamoto (1956a) or Hofstad and Doerr (1956) or Hall (1962). The test is performed by placing a drop of serum on a white porcelain or glass plate and mixing with a drop of stained anti-

gen. After the drops are mixed to make a spot about 2 cm. in diameter, the plate is rotated gently and the test read within 2 minutes. Turkey serum reacts more slowly than chicken serum in the test.

The tube agglutination test was found more reliable than the plate test by Jungherr et al. (1955). It was also found more reliable than the plate test in testing turkey serum (Hofstad, 1957b). The antigen prepared for the plate test can be used in the tube test when diluted 1:20 in phenolized (0.25 per cent) buffered saline (pH 7). For routine flock testing, it is suggested that the 1:12.5 dilution (.08 ml. serum plus 1 ml. antigen) be used. The test is read after overnight incubation at 37° C. Clearing of the supernatant fluid, with clumps of antigen covering the entire bottom of the tube, is indicative of a positive test.

The hemagglutination-inhibition (HI) test has been used by Fahey (1954), Fahey and Crawley (1954b), Crawley and Fahey (1957), Hall et al. (1961), Hofstad (1957b), and Yoder and Hofstad (1964a). The procedure of the HI test is essentially the same as the one used in Newcastle disease. The antigen used may be prepared by growing a suitable hemagglutinating strain of M. gallisepticum in broth. The antigen should be harvested at the peak of hemagglutinating (HA) activity. The organism is centrifuged out at 4,500 RPM for 1 hour in a refrigerated centrifuge. It is then suspended in 50 per cent glycerin and stored in the freezer. The HA titer is determined by making two-fold dilutions in 0.5-ml. amounts of buffered saline (pH 7) containing a 1:1000 dilution of normal serum. Washed 0.25 per cent chicken or turkey red blood cells are added in 0.5-ml. amounts to each dilution of the antigen. The test is read when the cell controls have sedimented, usually after 1 hour at room temperature. Agglutination is recognized by a uniform layer of cells covering the entire bottom of the tube, while in the negative tube a button of cells is found in the center of the bottom (Fig. 13.11). No elution occurs, so the test can be read at any time after 1 hour. If turkey cells are used, usually a two-fold higher titer is obtained than with chicken cells.
FIG. 13.11 — Hemagglutination-inhibition (HI) test. (Bottom row) Titration of antigen (M. gallisepticum). From left to right 4 tubes show agglutination of red cells; tube 5 is intermediate; tubes 6 and 7 show normal settling of red cells. (Top row) Negative serum in HI test. Tube 1 is serum control; tubes 2 through 5 show agglutination of cells; tube 6 is a saline blank with no red cells; tube 7 is cell control. (Second row from top) Positive serum-low titer; tube 1 is serum control; tubes 2 and 3 show complete inhibition; tube 4 shows partial inhibition; tubes 5-7 show no inhibition. (Third row from top) Positive serum — higher titers inhibition through tube 6.

The HI procedure can be used for both chicken or turkey serum When testing chicken serum, 4 HA units are used in the test, while 2 HA units can be used for turkey serum One HA unit is contained in the highest dilution of antigen which causes complete agglutination of 0 5 ml of 0.25 per cent red blood cells To set up the test, a series of 10 tubes are placed in a rack for each chicken serum sample to be tested. To tube 1 is added 0 8 ml of diluent, to tube 2 is added 0 5 ml of antigen containing 8 HA units, and to tubes 3 through 10 is added 0 5 ml of antigen containing 4 HA units Using a 1 ml. pipette, 0.2 ml of serum is removed from the serum sample and placed in tube 1 to make a 1·5 dilution of serum Tube 1 becomes the serum control The contents of tube 1 are mixed with the pipette, and a 0.5-ml. amount is transferred to tube 2 Using the same pipette, two-fold dilutions are continued through tube 10, discarding 0.5 ml from tube 10 after mixing has been done. Negative and positive serums should be included as controls A 0.5-ml. amount of 0.25 per cent red cell suspension is then added to each tube; the rack is shaken and set at room temperature for 1 hour after which the test can be read. A positive serum will inhibit agglutination to a certain dilution of serum. The results may be recorded as HI units (highest dilution of serum in which there is complete inhibition × the HA units used). For example, if the end point of inhibition is the 1:320 dilution, the serum would contain 320 × 4, or 1,280 HI units.

Prevention and control. Strict isolation of the flock should be maintained to avoid introduction of the disease into a clean flock. Breeding males should not be added to a flock unless they are from clean flocks as determined by negative serological tests for evidence of chronic respiratory disease. Replacements should be by day-old chicks originating from breeder flocks found free of chronic respiratory disease by serological tests.

Various inactivated vaccine preparations were reported to be of little value in pre-

venting M. gallisepticum infection by Prier and Dart (1951) and Adler et al. (1960). Attempts to immunize young birds with infective M. gallisepticum preparations inoculated intramuscularly have not been very satisfactory (Adler et al., 1960, and Donnermuth, 1962). Infective preparations inoculated via the respiratory route gave somewhat better protection against subsequent challenge (McMartin and Adler, 1961) and has been explored further to determine its effect on egg transmission of M. gallisepticum to their progeny (Olson et al., 1962, 1961, and Fabricant and Levine, 1963). The possible benefit of some reduction of egg transmission must be evaluated in the light of the hazard of perpetuation of the disease and the production of flocks which will be reactors when tested by the serologic procedures employed with most other control efforts.

Elimination of the disease in infected breeding flocks is a difficult problem, particularly when the flocks cannot be disposed of because of valuable inbred lines and families. One method is the hatching of small groups of a few hundred chicks in isolation and separating the clean groups from the infected ones by serological procedures. This procedure has been tried with some success by Dunlop and Strout (1956). The procedure is difficult to follow for most large breeding establishments where isolation areas are not available.

Attempts to eliminate egg transmission of the infection by monthly intramuscular injections of 200 mg. of streptomycin and dihydrostreptomycin in infected breeder flocks (Crawley and Fahey, 1955; Adler et al., 1956; Von Roekel et al., 1958) have not been found to be consistently effective. The use of other antibiotics for this purpose is currently being evaluated.

The dipping of warm hatching eggs in cold solutions of antibiotics, especially erythromycin and tylosin at approximately 400–1000 p.p.m., has been investigated as a means of reducing egg transmission of M. gallisepticum due to the effects of the absorbed antibiotic (Chalquest and Fabri-

cant, 1959; Levine and Fabricant, 1962; Olson et al., 1962; Stuart and Bruins, 1963; Hall et al., 1963; Yoder and Hofstad, 1964b). Alls et al. (1963, 1964) reported on the various factors affecting the permeability of dipped eggs and on the mechanics of the dipping process.

In general the dipping process has reduced, but not completely eliminated, the possibility of egg transmission. The influence on hatchability has not been consistently favorable, and the problem of bacterial contamination of dipped eggs has frequently been significant. The process is not recommended for widespread routine use at this time.

Although no consistently effective procedure has been developed for the control of M. gallisepticum infection in chickens, the application of one or more of the currently available procedures may lead to the establishment of clean replacement breeders. Strict attention must be given to sanitation and isolation procedures. The serological tests offer considerable aid in determining the M. gallisepticum status of flocks at various times, but cannot be used to eliminate infection from a flock by the testing and elimination of individual reactor birds, such as those used in the control of pullorum disease. Repeated random testing of 5–10 per cent of the birds in a flock may be adequate for preliminary investigations, but the testing of 100 per cent of the chickens in a flock near the time of sexual maturity probably is necessary to establish the status of breeder flocks. Moulthrop (1962) reported on the favorable performance of broiler chicks raised from M. gallisepticum-free breeder stock.

Brucellosis

Brucellosis is the name applied to the disease caused by the three species of the genus *Brucella*. In the initial stages of the infection there may be a bacteremia. After the bacteria recede from the blood stream, the disease continues in a subacute or chronic form with or without outward manifestations.

Occurrence. This disease is common in most countries in cattle, goats, swine, and man, and it also affects other mammals. It does not seem to be prevalent in birds. Veterinary literature contains several reports dealing with natural and experimental infection in various avian species. However, most of the diagnoses of brucellosis in fowl have been based on the agglutination test or merely on the fact

that the sick birds were or had been in contact with infected mammals. Very rarely have any of the Brucella been isolated from naturally infected birds. Therefore, the possibility exists that the outbreaks of disease diagnosed as brucellosis might have been caused by something else. Positive agglutination tests cannot be accepted as proof of Brucella infection. Such reactions might be due to continued ingestion of material contaminated with avirulent Brucella or they may have been nonspecific (Shklair and Stafseth, 1954).

History. According to several authors, brucellosis was first observed by Fiorentini in Italy in 1906. His diagnosis was based on the fact that 55 per cent of the birds reacted positively to the *Br. abortus* agglutination tests. Dubois (1910) reported on an outbreak of a disease in chickens, with a 75 per cent mortality, which he regarded as brucellosis because the birds were in contact with sheep suffering from *Br. melitensis* infection, and 60 per cent

[427]

of the affected birds reacted to the melitensis agglutination test in dilutions of 1.50 to 1:600. Zwick and Zeller (1913) unsuccessfully attempted to infect fowl by repeated subcutaneous, intramuscular, intraperitoneal, and intravenous injections of *Br. abortus.* Koegel (1923) tried to produce infection in chickens and pigeons by feeding and injecting large doses of *Br. abortus.* These birds gave agglutination reactions in titers of 1·200 to 1 1000 but showed no symptoms Emmel and Huddleson (1929) and Huddleson and Emmel (1929) claimed to have produced infection in fowl by feeding naturally infected milk, portions of an aborted fetus, and cultures They also claimed to have found natural Brucella infection in four flocks. A year later Emmel (1930b) found that turkeys, pheasants, ducks, and geese could be infected by feeding massive doses of the organism During the same year he found 16.5 per cent reactors to the agglutination test in a flock of 90 chickens (Emmel, 1930a). Many of these birds were in poor condition, and the egg production was low. According to Anguelov (1931) brucellosis is very prevalent, especially in modern poultry plants in Bulgaria. McNutt and Purwin (1930a, 1930b) tested 20 flocks with the agglutination test and found only a small percentage of reactors, none of them showing symptoms Attempts at producing infection by feeding and injection failed, as no symptoms were shown and no deaths occurred They further tested 10,000 birds in 69 flocks and obtained less than 2 per cent reactors, the highest percentage in any one flock being 12. Here again no evidence of illness was observed Strange and Beach (1931) failed to produce clinical disease in 32 chickens by feeding and injection of cultures. Gilman and Brunett (1930) tested 4 flocks of chickens, finding only a small percentage of reactors to the agglutination test. They conclude, however, that the evidence points to the presence of natural infection in farm flocks. McNutt and Purwin (1932) found laying pullets susceptible to infection with Brucella to the extent that egg production

was slightly decreased temporarily. In 10-day-old chicks no ill effects were produced. Van Roekel and his co-workers (1932) tested 25,202 chickens in 53 flocks with the agglutination test. The area covered represented approximately every county in Massachusetts. The total chicken population in these flocks was 70,479 birds. Two dilutions (1:25 and 1:50) were used. No reactors were found. Thirty flock owners had other livestock on the premises, and nine permitted the chickens to come in contact with the livestock. On three farms where reactors were found among cattle, the chickens were not allowed to come in contact with the cattle.

Two hens were given twelve feedings of a saline suspension of the organism during a period of 17 days, and agglutinins were detected 16 days after the first feeding. However, at no time were agglutinins well established in the blood stream, and the titer began to decrease two weeks after agglutinins were first detected. The birds were killed 28 days after the first feeding. Pathological and bacteriological findings were negative. Two hens were given three intraperitoneal inoculations with a saline suspension of the organism. Agglutinins were detected 7 days after the first inoculation, and a strong titer had been established at 4 weeks. At the end of 7 weeks the birds were killed, and no pathological or bacteriological evidence of infection was observed. Two males were given nine intraperitoneal inoculations with a saline suspension of the organism. Inappetence, somnolence, ruffled feathers, and decrease in body weight resulted. Agglutinins were present in the blood stream 9 days after the first feeding. Necropsies were performed 20 days after the first feeding, and *Br. abortus* was recovered from both individuals. One male was given three intravenous inoculations with a saline suspension of the organism. Clinical symptoms were observed. Agglutinins were established in the blood stream between the fourth and nineteenth days after the first inoculation. A necropsy was performed on the nineteenth day and *Br.*

abortus was recovered. These observations show that natural Brucella infection in chickens in Massachusetts appears to be of little, if any, significance. Agglutinins were produced when birds were fed and inoculated with saline suspensions of the organism. Repeated doses of the antigen were tolerated.

Beller and Stockmayer (1933) showed that chickens can be infected via natural and artificial channels. They found that the agglutination titer may be high 1½ years after infection. The organisms disappeared rapidly from the blood and organs and were not transmitted to the eggs. Young chickens were relatively resistant. Chickens injected with the organisms developed agglutination titers as high as 1:10,000. The organisms were re-isolated from twelve of thirty-two chickens. Five of these were injected intravenously, six intramuscularly, and one intraperitoneally. In most cases the organisms were obtained from the spleen, liver, and bone marrow. Thomsen (1934) exposed 2,677 chickens to natural infection. Only 15 per cent of his birds developed agglutination titers of 1:50. He concluded that brucellosis in chickens is of no importance in Denmark. Liddo (1934) exposed birds to infection with *Br. melitensis* of human origin and found pigeons more susceptible than chickens. Pavlov (1938) reported on his experiments with brucellosis in birds. He found that birds are less easily infected than mammals by natural and artificial methods, and that chickens are more susceptible than pigeons. Five of seven rabbits placed with infected chickens became infected and died within three months. Pure cultures of Brucella were isolated from them. None of three normal chickens and ten normal guinea pigs placed with infected chickens developed any evidence of infection. Eggs from chickens injected with massive doses of Brucella were found to contain the organisms only between the fourth and the fourteenth day after the injection. None of the injected birds developed any symptoms. The allergic and the agglutination tests were

found to be effective procedures in the detection of infection. The former gives the most pronounced reaction 24 hours after the injection of the test substance and is applicable three months after infection. The agglutination titer reached its maximum one month after infection. Two months after infection the agglutinins disappeared from the blood. Brucella injected in small doses (0.01 cc.) into eggs kept at ordinary temperature retained their virulence for one month and perhaps longer. Pagnini (1939) attempted to infect chickens by giving them gelatin capsules containing Brucella. The purpose of his work was to determine the role of chickens in the spread of brucellosis. Since he succeeded only when employing huge quantities of organisms, he concluded that chickens are of no practical significance in the spread of this disease. Felsenfeld *et al.* (1951) studied artificial Brucella infection in young chickens and found that intramuscular and intraperitoneal injection as well as feeding with Brucella caused bacteremia, fecal excretion of organisms, and significant agglutinin response. Cross reactions with *Vibrio cholerae, Proteus OX19,* and *Salmonella pullorum* were observed. Pen contact infection also occurred.

Anczykowski (1954) tested 29 flocks of chickens (2,384 individuals) with the agglutination test for brucellosis in Lower Silesia. Of these, 25 flocks (86.2 per cent) reacted positively in a 1:25 dilution or higher. The percentage of reactors in the various flocks varied from 1 to 55.5. Of 46 turkeys tested, 41.3 per cent reacted. Milk from infected cows or dairies was thought to be the source of infection. No correlation between positive and negative Brucella and *S. pullorum* agglutination reactions was established. The results, as a whole, suggest that the tests are specific.

Galuso and Rementzova (1955), in a review of research by Russian workers on brucellosis with special reference to this disease in wild animals, question the validity of the contention that goats and sheep are the original reservoirs of brucel-

losis They believe that the disease exists in wildlife including mammals, birds, reptiles, amphibians, and even fish. The role of ticks and mites in the spread of brucellosis is discussed.

Jurado et al (1951) studied experimental brucella infection in chickens and found that agglutinins were produced There were no signs or lesions of disease and the bacteriological findings were negative. They concluded that chickens in Brazil are scarcely, or not at all, significant as a reservoir of *Brucella abortus* and consequently of no epidemiological importance.

Spread. Felsenfeld *et al.* (1951) demonstrated transmission from artificially infected chicks to uninfected pen mates. The organism was found in droppings from infected birds. They also demonstrated that other diseases, such as coccidiosis or pullorum disease, increased the susceptibility of chickens to brucella infection. It appears that avian species become infected only under conditions of severe exposure or under other circumstances which decrease normal resistance. Spink (1956) noted the marked resistance of chickens to *Brucella abortus* and *Brucella melitensis* in contrast to the marked susceptibility of the chicken embryo. The conclusion was that "it is doubtful that chickens or other birds can be considered a significant reservoir of brucellosis." This conclusion is in agreement with that of Pagnini (1939).

Symptoms. Most authors have failed to observe symptoms of brucellosis in birds, and it is not certain that the symptoms described by others have actually been due to this disease. Dubois (1910) attributed the following symptoms to brucellosis. Between the months of March and June, 1910, 140 of 200 birds died. Young as well as old birds were affected. The disease appeared in a peracute and subacute form, killing birds in a few hours to 8 to 10 days. In the peracute form the birds died without previous symptoms. In the subacute form there was first loss of appetite; then the birds became weak and walked with difficulty. During the last 3 to 4 days they squatted and crowded together with ruffled feathers and drooping wings; they could easily be caught; sometimes they had greenish diarrhea. At last they became extremely emaciated. The following symptoms were recorded by Emmel and Huddleson (1929): "The birds first went off egg production and usually developed severe diarrhea. A gradually increasing paleness about the head, comb, and wattles, and emaciation occurred. Before death the birds became weak and often showed paralysis. The course of the disease ranged from 18 to 46 days."

Pathology. Dubois (1910) observed swelling of the spleen and liver and petechiae on the lungs. Emmel and Huddleson (1929) recorded the following anatomical changes: In the early stages of the disease the spleen was generally enlarged; later in the course of the disease it became shrunken. The liver was pale, mottled, and showed numerous brownish or gray foci on the surface; at death it had become pale and friable. The kidneys were also pale and showed some degeneration. The ovary was in the process of atrophy with flaccid ova of a dirty yellowish color. The intestines showed inflammation with some necrosis. In the duodenum there were irregular, elevated areas of cell infiltration. Beller and Stockmayer (1933) mention enlargement of the liver and very rare occurrence of necrotic foci in the spleen.

Diagnosis. The isolation and identification of one of the members of the genus Brucella constitute the only positive diagnosis. To be sure, agglutination and allergic tests have been employed successfully in experimental work. However, positive tests may be obtained with birds that cannot be proved to be infected by bacteriological examination, and Emmel and Huddleson (1929) found that the birds often gave a negative agglutination test in the last stages of the disease. Pavlov (1938) found that the agglutinins disappeared from the blood two months after infection, while Beller and Stockmayer (1933) found agglutinins in the blood a year and a half after infection. The difference between the

observations of Pavlov and Beller and Stockmayer may be due to a difference in the duration of the infection. According to Pavlov the allergic state remains longer than do the agglutinins in the blood. The allergic test was made by injecting a test substance, prepared according to Dubois (1933), into the skin at the point of the wing after removal of a few feathers.

Treatment and prevention. A number of drugs including the tetracyclines, chloramphenicol, the streptomycins, sulfadiazine, and corticosteroids have been found to be effective for treating brucellosis in man. They have not been tested in poultry. Although similar beneficial effect may be anticipated in treating poultry, it is doubtful if treatment would be indicated except under unusual circumstances. Since

birds can become infected with Brucella and may thus serve as agents of transmission, not only to other birds but to mammals as well, one should take steps to prevent fowl from being in contact with infected mammals. Good poultry hygiene demands that poultry should be confined within premises set aside for this type of livestock and not be allowed in barns, hog yards, etc. The practice of throwing dead chickens on the manure pile or elsewhere, where hogs or other birds may eat them, is to be condemned. Should a farm flock be found to be affected with brucellosis, the safest thing to do is to destroy the flock, disinfect the premises, and restock after leaving the poultry house and yards idle for several months. The testing and slaughter method is not applicable in poultry practice.

Anthrax

Anthrax is caused by *Bacillus anthracis* which in susceptible hosts produces an acute septicemic (bacteremic) infection characterized mainly by fever, slight coagulation and dark discoloration of the blood, swelling of the spleen, and edema and hemorrhages in various tissues.

Anthrax occurs rarely in birds. The rather frequent reports on cases of avian anthrax found in the literature of the nineteenth century were not based on bacteriological examinations, and it seems reasonable to assume that the great losses recorded may have been due to cholera or plague. The opinion expressed by Pasteur (1878), that chickens under ordinary conditions are resistant to anthrax, is shared by nearly all authors. Heusinger (1850) claimed that fowl could be fatally infected with anthrax. He is also responsible for the supposition that this disease occurred in epidemic form among chickens in Germany during the years 1832 and 1835.

EXPERIMENTAL WORK WITH AVIAN ANTHRAX

Artificial infection. Feser (1879) injected twenty-four chickens subcutaneously, and gave others anthrax bacilli in their feed for weeks without producing a single case of anthrax. Oemler (1879) fed anthrax material to eight ducks and twenty-eight chickens. The ducks sickened in 24 hours and soon died, while none of the chickens became ill. Only negative results were obtained by Koch et al. (1884) who gave their chickens large numbers of spores in feed. Perroncito (1885), Kitt (1886), and Hess (1887) were unsuccessful in their attempts to produce anthrax in chickens. In extensive experiments with anthrax in chickens, Hofherr (1910) failed to produce the dis-

ease even when giving large quantities of anthrax material to birds that were greatly weakened by starvation, thirst, cold baths, feeding of powdered glass, lime, vegetable diet, etc. By feeding a very large quantity of infectious material, one rooster that was already sick and one chick were infected. Fatal infection was produced, by feeding, in 25 per cent of the ducks and 100 per cent of the pigeons employed in his experiments. Thus, Hofherr showed that pigeons and ducks are susceptible to anthrax and that healthy chickens are ordinarily resistant but not always completely immune. Hunger and youth predispose to infection and so does lowered body temperature as was shown by Pasteur in 1878.

Mechanism of resistance. The mechanism of resistance of chickens to anthrax infection was studied very carefully by Wagner (1890). His work on forty-six chickens showed that under ordinary conditions chickens are resistant to this disease and that the immunity is due to phagocytic action of leukocytes. Anthrax bacilli can grow and maintain their virulence in the body of the chicken. The presence of the organism in the tissues is not without effect as shown by fever and cellular infiltration at the point of local infection. The resistance of chickens can be broken down by placing them in cold water baths for several hours or by giving them antipyrin or chloral hydrate. Submerging the chickens in a water bath for several hours resulted in death from anthrax in all of six birds. Antipyrin lowered the resistance to the extent that six out of eleven birds died of anthrax. In the case of chloral hydrate only one bird out of eight died. Lowering of the body temperature was shown to interfere with the mi-

gration of leukocytes to the point of infection. By use of the cold water bath the body temperature could be brought to a lower level and held there longer than by antipyrin and chloral hydrate. This may be the reason why the cold water bath reduced resistance more effectively than the other two agents. Möllhoff (1910) tried to determine the reason for the great resistance of birds to anthrax, and, on the basis of his experiments, drew the conclusion that the bactericidal action of lymph and blood play an important part, and that the high body temperature of the birds is less important.

NATURAL INFECTION

Anthrax in chickens. The only definitive diagnosis of anthrax reported in chickens was made by Serafimov (1961). The organism was isolated from the bone marrow of two dead hens. Lesions were not described. Oral administration of massive doses of the isolates to normal chickens failed to produce the disease. The hens had been in a yard in which a heifer had died of anthrax within the month. It was speculated that nutritional deficiencies existing in the birds at the time of infection, coupled with massive exposure, contributed to the infection. The nutritional deficiencies were not specified.

Anthrax in the ostrich. Epidemics of anthrax have been observed in the ostrich. The disease usually runs an acute course, but subacute cases occur, often terminating in recovery. Anthrax in the ostrich was first reported by Henning in 1894. Robertson (1908) reported on a case in an ostrich, and later Theiler (1912) and Ward and Gallagher (1920) described the disease in detail.

Pathology. Anthrax bacilli are present in all organs and do not differ, even with respect to pathogenicity, from those isolated from mammals. The following tissue changes may be observed: Slight coagulation and dark discoloration of the blood, increase in the fluid in the thoracic and abdominal cavities; petechial and larger hemorrhages in the pericardium, peritoneum, and mesentery; sometimes gelatinous infiltrations in the subcutaneous and deeper tissues; very frequently there is hemorrhagic enteritis; edematous swelling and hemorrhages in many places in the submucosa; not infrequently there may be a mass of blood in the lumen of the colon; the spleen, liver, and kidneys show swelling and congestion with blood; as a rule the lungs and stomach appear normal.

Anthrax in ducks. In birds other than the ostrich, anthrax appears only sporadically. Gerlach (1923) described a case of natural infection in a duck. This case occurred shortly after a few pigs had died of anthrax on the same farm. Ubertini (1939) reported on an outbreak of anthrax in ducks. These ducks were kept with about 100 chickens. There were two varieties of ducks — the common kind and five "mute" ducks (Cairina moschata) These five became ill and died while none of the others nor the chickens were affected. This outbreak occurred about 10 days following the death of a cow from anthrax.

Pathology. The following tissue changes have been observed: edematous swelling of the head, throat, and upper part of the neck, sometimes extending along the entire length of the esophagus, resembling a sac filled with fluid; the skin bluish-red in the affected areas; cyanosis of the mucosa of the head; gelatinous infiltration of the pharyngeal mucosa; inflammation of the intestinal mucosa; and other changes such as those recorded in the following description by Almeyew of a case of anthrax in an eagle.

Anthrax in birds in zoological gardens. Almeyew (1936) reported that anthrax had been observed in zoological gardens following the feeding of meat containing large numbers of anthrax bacilli. The source of the meat was unknown. He gave detailed results of a necropsy on the carcass of an eagle that had died of anthrax. This eagle was sent from the Zoological Garden in Kasan, eastern Russia, where it had died suddenly May 12, 1935.

The postmortem findings were mainly as follows: The nutritional state of the

carcass was fair; there was only slight muscular rigidity. The visible mucous membranes of the oral cavity showed a pale gray color and thick slimy coating, on the removal of which one could observe passive hyperemia. The tongue was covered with a slimy mass. The spleen was greatly enlarged; the capsule was distended and the pulp soft, discolored, and moist; in the pulp there were sharply circumscribed nodules from the size of pinheads to that of millet seed, reddish-brown or grayish-red in color; the cut surface was dull. The liver was enlarged, distended, and hyperemic; under the capsule and throughout the parenchyma there were hemorrhagic and necrotic foci. The cut surface was moist, and the vessels were distended. The kidneys were much enlarged, hyperemic, spotted, gray-yellowish-brown in color and were studded with hemorrhages and necrotic foci. The cut surface was moist, and the exuding blood was only slightly coagulated; the cortical and medullary layers were hyperemic and studded with grayish-red foci. The adrenals were edematous, hyperemic, and showed numerous hemorrhages; the serous membrane was dull and showed petechial hemorrhages. The lungs were edematous, hyperemic, and dark bluish-red in color; the surface was moist and studded with petechial hemorrhages. The pericardium was distended, of dull bluish-red color, and contained a yellowish-red transudate. The heart muscle was soft, being pale loam-colored and parboiled in appearance. The stomach was collapsed and grayish-blue; the vessels of the serosa were filled with blood; the stomach wall was thickened, the mucous membrane wrinkled, dark, and covered with mucus. The duodenum was dark red and showed numerous petechial hemorrhages, and the mucous membrane was covered with a reddish-brown mucous mass. The surface of

the large intestine was dark brownish-red, the walls thickened, and the mucous membrane covered with a brownish mucous layer.

Mollet (1913) and Urbian (1946) point out the possibility of mechanical dissemination of *B. anthracis* by free flying birds feeding on infected cadavers and offal.

Diagnosis. A presumptive diagnosis of anthrax in birds may be established by microscopic examination of stained films from blood, edematous fluid, or tissues in which anthrax bacilli usually are present in large numbers. It is well to confirm the diagnosis by cultural methods because of the possibility of mistaking saprophytic organisms for anthrax bacilli. The Ascoli precipitation test is a quick and reliable diagnostic procedure.

Treatment and prevention. The prophylactic value of vaccination of birds is unknown; the rare occurrence of the disease probably would not warrant its use even if effective. Specific antiserum as well as penicillin and oxytetracycline have proved effective in treating the disease in mammals. The value of these treatments for the disease in birds is unknown. Sanitary methods should be used to prevent spread of infection. Sick birds should be removed promptly, killed, and burned. Under no circumstances should dead birds be allowed to lie around so that other birds may pick at them or eat them. Contaminated ground should be fenced off, and houses should be thoroughly cleaned and disinfected. Litter, rubbish, and equipment of little or no value should be burned. Valuable birds that show no symptoms may be confined, preferably in houses with good cement floors where proper disinfection is possible. If the birds are few in number and of little value, it may be preferable to destroy the whole flock to facilitate the cleaning-up process.

Pseudotuberculosis

Pseudotuberculosis is a contagious disease caused by *Pasteurella pseudotuberculosis*, usually characterized by an acute septicemia of short duration, followed by a chronic focalized infection which gives rise to tubercular lesions in various organs.

History. The first isolation of the bacillus of pseudotuberculosis was made from a subcutaneous tubercular lesion on the forearm of a child by Malassez and Vignal (1883). Malassez published another report on this organism in 1884. Rieck (1889) reported on an outbreak of a disease in canaries which, according to the description of the symptoms, lesions, and characteristics of the isolated organism, must have been pseudotuberculosis. Several other authors have reported on this disease in canaries: Zürn (1884), v. Wasielewski and Hoffman (1903), Pfaff (1905), Freese (1907), Miessner and Schern (1908), Zwick (1914), Zeiss (1914), and van Heelsbergen (1927).

Woronoff and Sineff (1897) reported that they had found a case of pseudotuberculosis in a chicken. Truche and Isnard (1937) reported on an outbreak of this disease in a flock of adult chickens, and Schäfer (1939) reported on two cases in 14-day-old Leghorn chicks.

Bryner (1906) reported on an outbreak that occurred in 1904 involving tiger finches (*Habropya amandara* 1., *H. melpoda* vieill), butterfly finches (*H. phoenicotic* sws.), and Japanese titmice. Pseudotuberculosis in pigeons was reported by Dolfen (1916) and by Lesbouyries (1934). Reports on pseudotuberculosis in turkeys have appeared by Krage and Weisgerber (1924), Beck and Huck (1925), Lerche (1927a, 1927b), and Truche and Bauche (1929). Christensen (1927) isolated *Bact. pseudotuberculosis rodentium* (Pfeiffer) from pseudotuberculosis lesions of a variety of birds. Truche and Bauche (1933) have reported on an outbreak of pseudotuberculosis in fowls and pheasants, and according to Boquet (1937), they (Truche and Bauche, 1930) have also reported the disease in ducklings. Pseudotuberculosis in the swan was reported by Truche (1935). Urbain and Nouvel (1937) reported on

the disease in toucans (*Rhamphastos cuvieri* Gould and *R. ariel* Vig.). Beaudette (1940) reported on a case of pseudotuberculosis in a blackbird. Bacteriological investigations were made in the years 1938 to 1945 by Karlsson (1945) of 80 cases of pseudotuberculosis in domestic animals, 13 of which were found in birds, including 10 cases in turkeys.

Clapham (1953) observed pseudotuberculosis among stock-doves in Hampshire, England, during December, January, and February. In a search for the source of infection, *P. pseudotuberculosis* was isolated from a lark, a wood pigeon, a jackdaw, a rook, and a hare. The organism was also isolated from a rabbit in Hertfordshire and from two pigeons from Norfolk during this period. The authors had isolated the organism previously from gray partridge, pheasant, and bobwhite quail.

Van Dorssen (1952) isolated *P. pseudotuberculosis* from a bantam hen that had died. Multiple necrotic foci were seen in the liver and spleen. The organism was pathogenic for guinea pigs

Marthedal and Villing (1954) have observed seven outbreaks of pseudotuberculosis among pigeons in Denmark since 1950. There had been one case in a turkey and seven outbreaks in ornamental birds (canaries, snowbuntings, and waxwings). The organism isolated was *P. pseudotuberculosis rodentium*.

Thal (1954) studied 186 strains of *P. pseudotuberculosis*; of these, 33 were isolated from eight species of birds. All were biochemically identical; there were five serologically distinct groups. Most strains in group III produced thermolabile exotoxins, convertible to toxoids. Experimentally, anti-infection immunity was produced with live avirulent strains, thus protecting against infection with atoxic strains and subtoxic culture doses of toxic strains. Antitoxic immunity protected against toxin, and, to a degree, against infection with toxic strains, but not against infection with atoxic strains.

P. pseudotuberculosis was isolated from wild pheasants (*Phasianus colchicus*), partridge (*Perdix perdix*), and from a long-eared owl (*Asio o. otus*) by Borg and Thal (1961).

Etiology. The cause of this disease was first observed by Malassez and Vignal (1883) and was named *Bacterium pseudotuberculosis rodentium* by Pfeiffer (1890). Topley and Wilson (1936) and Breed *et al.* (1957) use the name *Pasteurella pseudotuberculosis*. In these two books and in the review of the literature on this disease by Beaudette (1940), there are complete descriptions of this organism. The earlier descriptions have been incomplete, making it difficult to identify newly isolated organisms on the basis of the available literature. Hutyra *et al.* (1938) claim that the designation, *Pasteurella pseudotuberculosis*, is a misnomer. However, this name is used here in conformity with the nomenclature accepted by the Society of American Bacteriologists.

The organism, which is not acid-fast, is a Gram-negative small rod 0.8 by 0.8 to 2.0 microns with rounded ends. Coccoid or long filamentous forms occur. It grows at 37° C. but optimally at 30° C. Motility develops at 30° C. or less and H antigens are produced if incubated at 22° C. Colonies after 24 hours at 37° C. are circular, 0.5 to 1.0 mm. in diameter, translucent and slightly yellow. Many types of media support growth. Acid but no gas is produced, sometimes only after prolonged incubation, from dextrose, maltose, mannitol, arabinose, xylose, rhamnose, salicin, and glycerol. Sucrose is sometimes fermented with acid production. It is H_2S+, indole—, methyl red+, catalase+, methylene blue is reduced, nitrates are reduced and ammonia is produced.

Occurrence. In the United States a definitely identified case of avian pseudotuberculosis in a blackbird was reported by Beaudette (1940) in New Jersey. Rosenwald and Dickinson (1944) studied several outbreaks of pseudotuberculosis in turkeys in Oregon. Mathey and Siddle (1954) isolated *P. pseudotuberculosis* from an 8-month-old tom turkey which died and showed typical lesions of pseudotubercu-

losis. There is a report by Kinyoun (1906) that may deal with this disease.

Kilian et al. (1962) isolated *P. pseudotuberculosis* from 9-month-old turkey hens. The organism was considered unusual in that it resembled *S. pullorum* on brilliant green agar, was agglutinated by *S. pullorum* antiserum, and after 24 hours incubation at 37° C. resembled *S. pullorum* by producing acid and no gas from dextrose and mannitol and failing to change lactose, sucrose, maltose, dulcitol, or salicin. Serum from sensitized guinea pigs, chickens, and turkeys which agglutinated hemologous antigen failed to agglutinate either *S. pullorum* or *S. typhimurium*.

Clark and Locke (1962) reported an epornitic of pseudotuberculosis in common grackles (*Quiscalus quiscula*), at a major icterid winter roost in Maryland. Mortality and morbidity were extensive and continued for several weeks until spring roost breakup. The occurrence of extensive infection in a large migratory bird population has major epizootiological significance.

In Europe, particularly in Germany and France, the disease must be fairly common, canaries and turkeys being the most commonly and severely affected. It usually occurs as a sporadic disease in individual flocks. One must remember that pseudotuberculosis often affects wild rodents, field hares and rabbits, and also domesticated rabbits and guinea pigs. Thus, such animals may be the source of infection in birds if direct or indirect contact is permitted.

Dissemination. The usual avenue of infection is the digestive tract. Skin injuries may also form portals of entry. Predisposing causes are apparently important since, as a rule, the only birds affected are those whose resistance has been lowered by inadequate feeding, exposure to cold, and worm infestation. Very young birds are particularly susceptible. During cold and wet weather in the fall, considerable losses may occur among young turkeys.

Pathogenesis. In susceptible birds the organism gains entrance to the blood stream through breaks in the skin or through the mucous membranes, perhaps mostly (but not necessarily exclusively) in the digestive tract. Thus, a bacteremia is established. Usually the bacteremic condition is of short duration, but the bacteria are not all destroyed. Some of them establish foci of infection in one or more organs such as the liver, spleen, lungs, intestines, and kidneys, giving rise to tubercular lesions. Such lesions have also been found in the mesentery and breast muscles.

Symptoms. The incubation period of artificial infection varies considerably with the virulence of the organism, the amount of inoculum, the avenue of introduction, and the host species. Sparrows and canaries are very susceptible and may die in 1 to 3 days from small doses of organisms injected subcutaneously or intramuscularly. Feeding of cultures is usually ineffective unless some intestinal inflammation is present to act as a predisposing influence. Canaries, given mustard seed for the purpose of causing intestinal irritation, have sickened 5 days after being given cultures by mouth, death resulting 2 days later. Judging from the various reports available, the incubation period may vary from 3 to 6 days in acute attacks and 2 or more weeks in chronic cases.

The symptoms also vary considerably. In very acute cases the birds may die suddenly without warning, or they may live a few hours or 2 to 3 days after showing the first symptoms. Such cases are usually marked by sudden appearance of diarrhea and the usual general manifestations of an acute septicemia. Usually, however, the course of this disease extends over 2 or more weeks, in which case the symptoms appear 2 to 4 days before death. In such cases the birds will show weakness, dull and ruffled feathers, and difficult breathing. Diarrhea is also a common symptom in such cases. Occasionally the disease will run a still more protracted course, when emaciation and extreme weakness or paralysis may be evident. Such manifestations as stiffness, difficulty in walking, droopiness, somnolence, constipation, and

discoloration of the skin have also been observed. In the early stages of the chronic form of the disease, the birds may eat normally, but the appetite is usually completely lost 1 or 2 days before death.

Anatomical changes. In highly acute cases the only changes observed are swelling of the spleen and enteritis. Subacute or chronic cases result in enlargement of the liver, spleen, kidneys, and lungs. Yellowish-white foci the size of millet seed may be found in the liver, spleen, lungs, kidneys, and breast muscles. There is usually severe enteritis, which is sometimes hemorrhagic. The serous cavities may sometimes contain more or less clear fluid.

Prognosis and diagnosis. The prognosis

is unfavorable. A definite diagnosis can be established only by isolation and identification of the organism since the symptoms and lesions are very similar to those of several other diseases such as fowl cholera, fowl typhoid, paratyphoid, spirochetosis, tuberculosis, and certain forms of the leukosis complex. In making a bacteriological examination, one must remember that the organism can be found in the blood in acute cases but must be sought in tissues in chronic ones.

Treatment and prevention. No medicinal treatment is available. Protective vaccination has not proved successful. Therefore, one must depend on the usual sanitary and hygienic procedures in combating this disease.

Tetanus

Tetanus is an acute infectious disease caused by the toxin of *Clostridium tetani* and is characterized by more or less persistent tonic spasms of some of the voluntary muscles resulting from an increased reflex irritability of the intoxicated motor nerve centers. The toxin is elaborated in infected wounds providing suitable conditions for growth and reproduction of the tetanus bacillus. Anaerobic wounds in which there is necrotic tissue or blood effusion are particularly favorable.

Occurrence. Birds are comparatively very resistant to tetanus. Knorr (1899) has shown that the lethal dose of tetanus toxin for fowl per kilogram of body weight is 200,000 times greater than that for the horse. This fact no doubt accounts for the scarcity of reports dealing with tetanus in birds.

Tetanus or tetanuslike disease in birds. Dreymann (1894) reported on a case of illness resembling tetanus in a turkey. Four to 5 days after having been bitten by a dog, this bird showed a clumsy and stiff gait, the neck was extended, the neck muscles were hard, and there was trismus. On the third day the entire body was rigid, the wings were held tightly against the body, the feathers were ruffled, the nictitating membranes and eyes protruded, there was almost complete trismus, and the bird died.

A case of tetanus in a young goose was described by Funck (1919). The symptoms were mainly trismus and difficult locomotion. The necropsy revealed a perforation of the stomach wall, caused by an iron wire, which in the author's opinion was the portal of entry.

Russell (1937), of Portsmouth, England, reported on a rapidly fatal case of illness in a young child, diagnosed as tetanus. An investigation revealed that the garden in

which the child played was fertilized exclusively with pigeon manure. Tetanus bacilli were recovered from two of four soil samples, two samples of dirt or litter from the pigeon loft, and from the excreta of one pigeon

On July 15, 1910, Dr J. H Scamman of the Angell Memorial Hospital, Boston, Massachusetts, wrote me in part as follows: "It is a six-months-old domestic bird (goose) and has all the appearances of lockjaw. It cannot open its jaws at all, and if they are forced apart, they close by themselves."

Another case of a tetanuslike disease in a goose was reported to the Michigan Agricultural Experiment Station, October 4, 1910. This goose was three months old and showed typical symptoms of tetanus.

In none of these four cases was there

any bacteriological work done to prove the identity of the disease.

Diagnosis. A positive diagnosis of tetanus can be established only by the isolation and identification of the organism. This is not always possible due to the difficulty in locating the focus of infection and the fact that tetanus bacilli often soon disappear from infected wounds. Remedial effects obtained by the administration of tetanus antitoxin would constitute evidence of some diagnostic value.

Treatment and prevention. Antitoxin given in large doses may be of some value in the very early stages of the disease in mammals. There is no work showing the effect of antitoxin treatment in birds. The infrequent occurrence of tetanus in birds makes special preventive measures superfluous.

Vibrio Infection

Vibrio infection is an acute infectious disease which resembles fowl cholera with respect to symptoms and gross pathology.

History. This disease was first reported by Gamaleia (1888) who observed it several times during the summer near Odessa. Krause and Windrath (1919) observed the disease in Germany in newly imported sunbirds (*Leiothrix luteus*). According to Hutyra et al. (1938), Czukas has observed it in Hungary in fattened geese.

Frazer (1961) isolated a strict anaerobic vibrio from liver and other tissues of an adult King penguin. The isolate failed to infect embryonating eggs and was indole, H_2S and catalase negative. It did not resemble either *Vibrio metchnikovi* or the vibrio responsible for avian vibrionic hepatitis.

Cause and dissemination. The cause is *Vibrio metchnikovi* (Gamaleia), also

called the paracholera vibrio. This organism is a small, bent, comma-shaped microbe that can be easily cultivated. It is very motile and is Gram-negative. Culturally and biochemically it resembles almost fully the vibrio of Asiatic cholera. These two organisms are also related antigenically as is shown by cross immunity. According to Czukas the organism infects birds that are weakened by poor hygienic conditions and by fattening. *Vibrio metchnikovi* is also pathogenic for pigeons and guinea pigs. Chicks can easily be infected per os. Older chickens and rabbits are very resistant. It appears that stagnant water and other materials contaminated with droppings of infected birds may serve as sources of infection.

Symptoms. In chickens the symptoms resemble those of fowl cholera. Vibrio infection is generally less acute and the body temperature is only slightly elevated, while

in fowl cholera it is usually high, e.g., 43° to 44° C. The birds observed by Gamalela sat crowded together and disinterested, with ruffled feathers. Diarrhea was a constant symptom. The birds usually died in 2 to 3 days. In the sunbirds the disease was so acute as to cause the death of several hundred birds in a few days.

Pathology. The organism causes enteritis and gastroenteritis which is sometimes hemorrhagic. It may enter the blood stream and give rise to necrotic processes in the liver and lungs. In young chickens and sunbirds the organism appears in the blood in large numbers, but in adult chickens the blood smears are mostly negative.

Diagnosis. A differential feature in the pathology of fowl cholera and vibrio infection in chickens is that the latter produces no or few petechial hemorrhages in the intestinal tract and only slight or no changes in the organs. A definite diagnosis can be made only by the demonstration of the organism in the blood and preferably by the isolation and identification of the vibrio. Cultures should be made from the blood and organs showing lesions. The bacteriological diagnosis is complicated by the fact that the organism is generally confined to the lumen of the intestinal tract.

Treatment and prevention. Modern drugs have not been evaluated for either prophylaxis or therapy of the disease. The considerable number of drugs known to be effective against other vibrionic infections suggests possible activity of some of these drugs against *Vibrio metchnikovi*. Prevention must depend on the usual sanitary measures employed in the control of diseases of similar epidemiological nature.

Avian Vibrionic Hepatitis

Avian vibrionic hepatitis is a contagious disease of chickens which ranges in clinical course from acute to chronic. All ages of chickens are susceptible, but the disease is diagnosed chiefly in semimature and mature stock.

Tudor (1954) reported a disease, presumably avian vibrionic hepatitis, and stated that the disorder was observed by Beaudette and Hudson as early as 1933. Marthedal (1953) described a severe degenerative hepatitis occurring chiefly in birds under three months of age, usually accompanied by typhlitis and splenomegaly. No infectious agent was demonstrated. Delaplane et al. (1955) were the first to report an infectious agent as being responsible for the disease. Hofstad (1956) and Winterfield and Sevoian (1957) also reported the occurrence and infectious nature of the disease. Hofstad et al. (1958) and Peckham (1958) simultaneously classified the causal agent as a vibrio.

Distribution. The disease has been identified in the major poultry producing areas of the United States and Canada, in Japan (Miura, 1962), in Germany (Fritzsche and Gerriets, 1962), and in Scotland (Wilson, 1963). Reports of the northeastern state diagnostic laboratories for 1957 through 1961 (Angstrom, 1958, 1959, 1960, 1961, 1962) show that the annual incidence of avian vibrionic hepatitis ranged from 1.26 to 1.85 per cent of all avian cases submitted for diagnosis. Most of the diagnoses were made in flocks over 20 weeks of age

FIG. 14.2 — Chicken embryos at 19 days of age. Normal embryo in center. Two embryos, inoculated with hepatitis agent at 11 days of age, have liver enlargement and necrosis. (Hofstad et al., 1958, Avian Diseases.)

with very few being made at less than 4 weeks of age.

Etiology. The causative agent was first isolated in the yolk sac of 5- to 7-day embryonating chicken eggs by Delaplane et al. (1955). Peckham (1958) and Hofstad et al. (1958) were the first to identify the agent as a vibrio. It is a micro-aerophilic, Gram-negative, motile, comma or S-shaped rod that is occasionally spiral in form (Fig. 14.1). Older cultures on agar consist chiefly of coccoid forms.

Most embryos infected via the yolk sac at 5 to 7 days of age die between the 2nd and 6th day after injection. The vibrio develops in high concentration in the yolk of infected embryos regardless of the route of infection; amniotic and allantoic fluids contain few or no vibrios (Winterfield et al., 1958). Grossly visible liver necrosis and enlargement of the spleen occurs in embryos inoculated into the allantoic sac at 10 to 15 days of age (Fig. 14.2) (Hofstad et al., 1958) as well as in late deaths following yolk sac inoculation.

The organism has been grown in cell-free mediums. Hofstad (1956) grew the agent in a chicken-serum enriched, chicken infusion broth. Peckham (1958) isolated the organism on chicken infusion agar incubated in a 10 per cent CO_2 atmosphere as well as by inoculating a few drops of bile from infected chickens on blood agar plates incubated at 37.5° C. in a Brewer anaerobic jar containing 10 per cent CO_2, 63 per cent methane, and 27 per cent air. The following characteristics of an isolate examined in some detail were reported by Peckham (1958): glucose −, xylose −, mannitol −, lactose −, sucrose −, maltose −, MacConkey + light, S.S. −, hemolysis −, citrate −, urea −, nitrate −, indole −, H_2S TSI paper 2 + butt −, MR/VP − / −, gelatin −, litmus milk −, spores −. O_2 requirements microaerophilic, temperature 37° to 42° C., pigment slight yellow, oxidase +, motility +, catalase 2 +. Whenham et al. (1961) secured satisfactory growth in semisolid thiol medium with consistent fermentation of dextrose when added; an indicator was added after 24 or 48 hours incubation. Occasional slight fermentation of lactose, maltose, and mannitol was secured with the same system but not of sucrose or dulcitol. H_2S was not formed from Kligler's iron agar.

The agent is sensitive to streptomycin, dihydrostreptomycin, tetracycline, oxytetracycline, chlortetracycline, magnamycin, furazolidone, neomycin, erythromycin, sulfamethazine, sulfaquinoxaline, and thallium acetate. It is resistant to bacitracin, polymixin B sulfate, and chloramphenicol and penicillin except in large amounts. Sensitivity differences between strains probably occur (Winterfield et al., 1958; Hofstad et al., 1958; Whenham et al., 1961).

The bacterium is filterable through a Selas 02 filter but is retained by the 03 Selas filter (Hofstad et al., 1958). It passed through the 0.45 millipore filter but was retained by the 0.30 membrane filter as well as by Seitz EK filters (Winterfield et al., 1958).

Hofstad et al. (1958) found the organism viable after storage in infected embryo yolk for 2 years at −25° C. Peckham (1958) found the agent viable 20 months after lyophilization. Winterfield et al. (1958) found infective yolk viable after 2 but not 3 weeks at 37.5° C. At 25° C. another strain remained viable for only 12 days.

Peckham (1958) noted that some isolates were readily adapted to culture on artificial media, whereas other isolates were difficult to subculture and in some cases were lost after 3 or 4 transfers. Winterfield et al. (1958) found that isolates lost pathogenicity after serial yolk sac passage.

Hosts. Natural infections have been recorded only in chickens. Day-old poults were experimentally infected by Peckham (1958) and Winterfield et al. (1958). The latter group reported death, with resolation from the liver of a 4-month-old rabbit 5 days post intraperitoneal injection. Infection was not established in adult hamsters or in mice injected intraperitoneally. Peckham (1958) injected white Swiss mice intracerebrally, produced nervous symp-

ions with some colonies and re-isolated the organism.

Signs and mortality. The usual clinical signs in affected flocks indicate a chronic infection. Affected chickens exhibit listlessness, a scaly drawn comb, loss of flesh, and frequent diarrhea. Peckham (1958) and Sevoian et al. (1958) observed a lag in egg production in affected pullets and as much as a 25 to 35 per cent drop of production in laying flocks. In laying flocks signs of an acute infection may occur with mortality of birds in excellent flesh which have laid eggs within the past 48 to 72 hours. Moore (1958), using a laparotomy technique, observed that some birds with signs and lesions spontaneously recovered. Mortality was reported as high as 5 per cent by Peckham (1958) and 10 to 15 per cent by Sevoian et al. (1958).

Pathology. The liver is the primary site of gross lesions. Usually the liver is firm,

having irregularly shaped, grayish-white areas on the surface (Fig. 14.3). In more acute cases the liver is swollen, congested, and studded with necrotic areas. Hemorrhagic areas may also be present, giving the liver a mottled appearance. Massive subcapsular hemorrhages may occur which occasionally rupture and cause death from frank hemorrhage. In chronic cases, varying degrees of ascites and hydropericardium may be present. The entire liver is not always involved; only part of a lobe may show degenerative areas.

The microscopic lesions have been studied extensively by Sevoian et al. (1958). Sections of liver may reveal generalized congestion, localized hemorrhages, and areas of necrosis. Infiltration of the liver with lymphocytic and heterophilic cells with bile duct proliferation is common. Figure 14.4 illustrates the type of lesion which may be found. The heart of young chickens may be edematous and contain areas infiltrated with mononuclear cells. Embryo livers exhibit focal necrosis, occasional aggregates of heterophils accompanied by bile duct proliferation, bile stasis, and regenerating liver cord cells about the hepatic vessels (Casorso and Jungherr, 1958).

Transmission. Delaplane et al. (1955) successfully infected day-old chicks by feeding as well as by subcutaneous and intraperitoneal inoculation. Sevoian et al. (1958) confirmed these findings and found lesions as early as 48 hours after injection of 2-day-old chicks, with hepatic lesions being most pronounced between 3 and 12 days. Signs were not usually prominent and frequently were absent. In older chickens gross lesions were not seen until 5 to 15 days after inoculation, with lesions persisting for at least 9 weeks at which time the vibrio was still recoverable.

Sevoian and Calnek (1959) incubated over 1,200 eggs from experimentally infected chickens and found 66 per cent fertile, of which 13 per cent died by the twentieth day of incubation. The agent was not isolated from yolk sacs of the latter by culture on blood agar and embryo

FIG. 14.3 – Liver of a field case illustrating irregularly shaped degenerative areas found in avian vibrionic hepatitis. (Bennett, Iowa Vet. Diag. Lab.)
FIG. 14.4 — Liver section of field case of avian hepatitis. Hemorrhage around central vein. Light area to right of center is devoid of liver cord cells and contains erythrocytes, heterophiles, and some lymphocytes. X96. (Hofstad, Iowa State University)

inoculation. Hofstad et al. (1958) inoculated the allantoic sac of 15-day-old embryos; 34 of 52 hatched, some of which had liver necrosis although the birds appeared clinically normal. Narotsky and Taylor (1958) found gross and microscopic lesions indistinguishable from those produced by the vibrio in chicks hatched from infected flocks. Limited isolation attempts were negative. Additional work appears necessary before the possible role of egg transmission of the disease can be determined. The organism is presumably excreted in the feces; ingestion of material contaminated by feces is assumed to be a major means of transmission.

Diagnosis. Several other diseases bear a close clinical and gross pathological similarity and must be eliminated in differential diagnosis. Most prominent of these are pullorum disease, fowl typhoid, staphylococcosis, and leukosis.

A diagnosis based on isolation and characteristic gross and microscopic pathology is preferred. Considerable caution is indicated as: 1. isolation is not always successful, 2. slight histological changes may not be sufficiently characteristic to be diagnostic, and 3. presence of the organism

with characteristic pathologic changes does not necessarily indicate a flock problem. Thorough appraisal of the history as well as thorough examination of multiple specimens helps to overcome these difficulties.

The vibrio may be isolated from many sites including the heart, liver, spleen, pericardial fluid, kidneys, and bile. Bile is preferred and may be aspirated from the gallbladder and dropped without germinating on a blood agar plate. Plates are incubated under 10 per cent CO_2 for 72–96 hours. Demonstration of typical Gram-negative vibrios in resulting growth is usually considered adequate. Injection of bile in 0.1 ml. amounts into the yolk sac of 5- to 7-day-old embryos is a superior method of isolation (Sevoian and Calnek, 1959). Bacterial contaminants may be controlled by the use of bacitracin and polymixin B (Winterfield et al., 1958). Yolk material from embryos that succumb may then be used for direct plating or repassage. Motile vibrios may at times be demonstrated in bile as well as in yolk material from infected embryos; only positive findings have significance (Whenham et al., 1961). It is worthwhile to point out the possibility that other as yet unrecognized

vibrios with or without pathologic significance may exist in bile or other organs of the bird. Lack of simple means of precise identification of the vibrio increases the importance of auxiliary diagnostic criteria.

Chicks are particularly susceptible during the first days of life and serve as an excellent means of confirming isolations. Injection into the yolk sac or peritoneal cavity usually produces lesions within 3–5 days. However, chicks seldom appear clinically ill and must be sacrificed to demonstrate infection. Focal hepatic necrosis and hydropericardium are usually exhibited.

No serologic tests are available for diagnosis.

Treatment. It has already been indicated under the section on etiology that the organism is sensitive to a large number of antibiotics and to several chemotherapeutic agents. Winterfield et al. (1958) reported extensive prophylactic and therapeutic trials in chicks. Prophylactic activity was demonstrated by chlortetracycline, oxytetracycline, and furazolidone administered in the feed, by sulfaquinoxaline and sulfamethazine in water, and by streptomycin by injection. Oxytetracycline, furazolidone, and streptomycin appeared superior to the others tested. On a therapeutic basis in chick tests, furazolidone and streptomycin appeared more effective than the others. Streptomycin at a dosage of 5 mg. intramuscularly per chick was compared to 0.022 per cent and 0.044 per cent

furazolidone in the feed. At the lowest level (200 gm. per ton) furazolidone was more effective than streptomycin. Sevoian and Calnek (1959) compared the prophylactic activity of 300 gm. per ton of furazolidone in the feed for 5 consecutive days to a 250 mg. single injection of dihydrostreptomycin in adult White Leghorn hens. A second trial compared the same dosage of dihydrostreptomycin to 250 gm. per ton furazolidone fed for 5 consecutive days to mature Rhode Island Red hens. A high degree of efficiency was indicated following each of the treatments. Relapse or reinfection was noted in the trials and has also been noted with some frequency in field flocks. Furazolidone in the feed ration at 0.022 per cent (200 gm. per ton) for a 10- to 12-day period is recognized as a standard treatment. Streptomycin by injection is also used at a level as high as 50 mg. per pound of body weight.

Prevention and control. Moore (1958) and Winterfield et al. (1958) were unable to demonstrate immunity in infected chickens. Although limited trials so far have been negative, egg transmission cannot be excluded. Until more is known concerning the source of infection, means of transmission, and reservoirs of infection, prevention must be based on sound management practices and sanitation. Treatment with furazolidone or streptomycin offers limited control capability; the potential for prophylaxis by continuous low level administration of drugs has not been adequately explored.

Borrelia Anserina Infection (Spirochetosis)*

The disease, caused by *Borrelia anserina* (Breed *et al.*, 1957), was first described by Sakharoff (1891). The organism, which he named *Spirochaeta anserina*, was responsible for an extensive epornitic among geese in the Caucasus. Other names which have been used are *Spirochaeta gallinarum*, *Spirochaeta anatis*, and *Treponema anserina*.

Distribution. The infection has been identified in many countries of the world, but apparently not further north of the equator than 54 to 60 degrees parallel (Zuelzer, 1936). Its distribution is similar to that of the tick *Argas persicus* Oken 1818 which is its major vector. Although the tick is prevalent in the southern part of the United States, the disease is not commonly found in this region. Hoffman and Jackson (1946) identified in turkeys the first authentic case of avian *B. anserina* infection in the United States. It was also identified in turkeys in California by McNeil *et al.* (1949) and by Loomis (1953). Francis (1956) and Rokey and Snell (1961) reported the disease in chickens in New Mexico and Arizona respectively. Burroughs (1947) identified the disease in a cockerel used to feed ticks (*A. persicus*) obtained from Texas. Mathey and Siddle (1955) reported a natural infection in Mongolian pheasants on a California game farm. Mathey and Zander (1955) reported a spirochete isolated from cecal nodules of chickens which is thought not to be *B. anserina* but probably the same as the unnamed organism reported by Steinhaus and Hughes (1947).

Etiology. *B. anserina* is reported to vary in length from 6 to 30μ with great variations noted within preparations. McNeil *et al.* (1949) report an average length of 14μ (7 to 21μ) with 6 spirals. The organism is motile, stains readily with aniline dyes (in contrast to *Leptospira* and *Treponema*), reproduces by binary fission, and is soluble in 10 per cent ox bile and 10 per cent saponin.

Hosts. The organism is infectious for a wide variety of birds. Literature summaries by Knowles, *et al.* (1932) and by El Dardiry (1945), indicate such discrepancy between the findings of different investigators as to the degree of susceptibility of different species. El Dardiry (1945) suggests that genetic resistance may be an explanation. Antigenic differences

quite likely occur and possibly not all isolates have equal pathogenicity for all hosts.

Mild infections have occasionally been produced in rabbits, but mice, rats, guinea pigs, dogs, mules, horses, and sheep have been found refractory (El Dardiry, 1945; McNeil et al., 1949).

Transmission. Marchoux and Salimbeni (1903) first demonstrated the tick *A. persicus* to be a primary vector of *B. anserina*. The infected tick lays infected eggs which hatch into infected larvae. Larvae and nymphs apparently are more infective than are adults (Sreenivasan and Sankaranarayan, 1943). The review by El Dardiry (1945) indicates that *A. mineatus* and *Ornithodorus moubata* may also serve as vectors. Hungerford and Hart (1937) demonstrated that the red mite *Dermanyssus gallinae* may be a vector; *culex* mosquitoes have also been incriminated (Zuelzer, 1936; El Dardiry, 1945).

The disease may also be transmitted in the absence of vectors. Sreenivasan and Sankaranarayan (1943) reported transmission between chickens by cohabitation. The infections in California turkeys (Hoffman and Jackson, 1946; McNeil et al., 1949; Loomis, 1953) were not traced to vectors. Infected droppings were believed to be the major means of transmission within the flocks. A California strain of *B. anserina* was maintained in *A. persicus* by Hsiang and Packchanian (1951).

Neither egg transmission of the organism nor carriers have been reported.

Signs and lesions. The incubation period is largely dependent upon dosage, and may be as little as 1 day. The incubation period of natural infections ranges from 3 to 8 days. A marked rise in body temperature is accompanied or soon followed by the appearance of *B. anserina* in peripheral blood. Acutely affected birds show cyanosis of the head, marked depression, increased thirst, and diarrhea. Subacute or chronic cases are reported. A mortality of 50–60 per cent may occur chiefly between 3 to 15 days post infection. Although young birds are generally con-

sidered to be more susceptible than old birds, Rokey and Snell (1961) found the opposite to be true.

Gross lesions are found chiefly in the spleen and liver. In terminal cases the spleen is enlarged as much as six times normal and is mottled as a result of hemorrhage. The liver is enlarged, frequently bile stained, friable, and studded with small necrotic foci. The heart may present a parboiled appearance. A mucoid enteritis is often present. Dehydration and emaciation is marked. Extreme weakness, or possibly paralysis, may be seen in chronic infection.

Histopathological changes in the chicken have not been extensively studied. Rokey and Snell (1961) describe the changes as follows:

"In the kidneys, collecting tubules had undergone coagulation necrosis. Capillaries were engorged. Hemorrhagic infarcts in various stages of resolution were encountered. Lymphocytic infiltration of interstitial tissue was a common finding.

"In the liver, there were subcapsular hemorrhages. Multiple areas of focal necrosis and a cellular infiltration of the hepatic triads were seen. The cellular infiltration consisted of lymphocytes and large phagocytic cells. The venous system had a characteristic lymphocytic proliferation zone. The large bile ducts were surrounded by a wide zone of lymphocytic proliferation. Fatty degeneration of varying degrees was observed.

"Large areas of hemorrhage were prominent in the spleen, and necrosis was observed in centers of reticular cell groups. The general splenic structure was intact, but an active proliferation of lymphocytic elements gave the splenic structure an abnormal appearance.

"Localized nests of lymphoid cells were seen between the cardiac muscle fibers. There was little apparent damage to the cardiac muscle.

"Congestion, hyperemia, and pneumonic areas were observed in the lungs. In some of these areas, lymphocytic infil-

trations completely obliterated the normal lung structure."

Quite similar histopathological changes have been described in turkeys by McNeil et al. (1949).

Diagnosis. Diagnosis is ordinarily dependent upon demonstration of the organism. It may be demonstrated in blood smears by the Giemsa technique or may be seen in wet mounts by dark-field illumination. Appreciable numbers are present within the first several days of the disease, but disappear at crises after clumping in large aggregates as a result of the development of agglutinating antibodies. Death may be due to the formation of emboli by the agglutinated organisms (Lavaditi, 1904; DeLamater et al., 1952). Cultivation on artificial mediums has met with mixed success and has been summarized by McNeil et al. (1949) and Saurino and DeLamater (1952). Knowles et al. (1932) grew the organism in fertile chicken eggs. McKercher (1950) secured improved results by yolk sac injection of 6-day embryos. In the latter technique, material must be harvested from live embryos in a manner to allow collection of chorioallantoic fluid and embryonic blood, as B. anserina is found chiefly in the latter. Such harvests were demonstrated to remain viable for 2–3 weeks when held at 4° C.

El Dardiry (1945) maintained B. anserina in virulent form for 30 days in a refrigerator after separation from clotted blood taken from infected chickens. This method maintained virulence better than if maintained in citrated blood (Sreenivasan and Sankaranarayan, 1943). McNeil et al. (1949) found spleen, heart, and liver infectious after storage at 32° F. for 31 days.

Nobrega and Reis (1947) reported finding the organism by dark-field illumination in heart blood of 85 per cent of chickens which died after experimental infection. They described a method, given in more detail in Chapter 41, of testing for antibodies which greatly improved diagnostic accuracy in those specimens in which the organism was not found.

Lesions are not diagnostic unless the organism is demonstrated in tissues by an appropriate stain such as Levaditi or by the slow method of Giemsa.

Treatment and control. Early work on immunity development and immunization methods was reviewed and extended by El Dardiry (1915). A solid immunity develops in survivors; relatively small amounts of serum from such birds may be used for passive immunization. Active immunization has been accomplished with antigens prepared and used by a variety of means including formalin inactivation of blood or emulsified liver and spleen, infectious blood inactivated by immune serum, and by administering immune serum prior to active infection. Immunity by several of these methods has lasted for at least 18 months. Nobrega and Reis (1941) prepared a vaccine by infecting 12-day-old chicken embryos. They harvested the embryo, membranes, and amniotic fluid after 5 days, diluted with saline to 30 ml. per egg, and inactivated with 0.5 per cent formalin. The suspension was filtered after 24 hours of refrigeration. A 25 per cent dilution of the stock suspension was used intramuscularly in a 1 ml. dose. They considered this vaccine to be equal in efficacy and more economical than that made from blood or organs of chickens.

A variety of drugs have been demonstrated to have therapeutic value. Earlier reports were summarized and additional compounds were tested by Packchanian (1950) and by Hsiang and Packchanian (1951). The following compounds have been proven to be effective in vivo: atoxyl, salvarsan, myosalvarsan, "spirocid," neoarsphenamine, mapharsen, tryparsamide, 4-carbamidophenyl di (1'-carboxyphenyl 2' thio) arsenite, and the antibiotics penicillin G, oxytetracycline, chlortetracycline, bacitracin, chloromycetin, streptomycin, and dihydrostreptomycin. Of the antibiotics, Hsiang and Packchanian (1951) found oxytetracycline to be most effective. A single injection of 0.1 mg. per 50 gram chick was found to be curative. Compa-

rable results were secured with 1 mg. chlortetracycline or bacitracin and with a 10 mg. dosage of streptomycin or penicillin.

Control or eradication of vectors will substantially aid in preventing the disease. Spread of infection within a flock should be minimized by sanitary disposal of cadavers and droppings.

Listeriosis, Botulism, Erysipelas, and Goose Influenza

Avian Listeriosis

Sporadic cases or outbreaks of septicemia caused by the bacterium *Listeria monocytogenes* have been reported in chickens and other birds by a number of workers. The same organism also causes disease in mammals, including man.

Listeria was first isolated by Murray *et al.* (1926) from an outbreak of disease in laboratory rabbits and guinea pigs in England. It was first found to be the cause of an encephalitis of sheep by Gill in 1931 in New Zealand, and has since been described from ruminants by a number of investigators.

Listeria is found throughout the world. It has been found to cause spontaneous disease or be present in at least 35 species of mammals, 17 of birds, pond reared trout, ticks, crustacea, stream water, mud, sewage and silage (Gray, 1963). Infected mammals include the domestic rabbit, hare, guinea pig, chinchilla, gerbil, lemming, vole, sheep, ox, goat, deer, pig, horse, dog,

cat, skunk, fox, mink, raccoon, ferret, and man. A great many papers have been written on this organism. Among recent reviews are those of Seeliger (1961), Gray (1958, 1963), Jones and Woodbine (1961), Kampelmacher (1962), and the Office International des Épizooties (1961).

Listeria was first isolated from chickens in New Jersey by Ten Broeck in 1932 according to Seastone (1935), who also reported on the disease. Gray (1958) listed 43 other reports from chickens in the United States, Canada, England, France, Germany, Sweden, the Netherlands, Belgium, Argentina, Finland, Czechoslovakia, Russia, Australia; it has also been found in chickens in Italy (Sparapani, 1916).

Listeriosis has been found in geese in Germany, Hungary, Russia, and Ceylon; in ducks in Germany and France; in turkeys in the United States; in pigeons in Czechoslovakia and the Netherlands; in canaries in Canada, Norway, and the Netherlands; in a parrot in Czechoslovakia; in a blue eagle in the Leipzig zoo; in the capercaillie
FIG. 15.1 – Listeria monocytogenes from chicken. Gram stain. ×990.

(*Tetrao urogallus*) in Sweden; in the partridge in France; and in a snowy owl in Canada (Gray, 1958; Levine, 1959; Jones and Woodbine, 1961). More recently, Listeria has been isolated from canaries and chickens in the Netherlands by Kampelmacher (1962) and Kampelmacher and Jansen (1961); from chickens, partridges, pheasants, a duck, a pigeon, and a canary in France by Lucas (1961) and Lucas et al. (1962); from poultry in Sweden by Nilsson and Karlsson (1959); from the chicken, goose, crane, and ptarmigan in Finland by Stenberg (1961); from chickens in Germany by Train (1961, 1962); and from the diamond dove (*Geopelia cuneata*), Swainson's lorikeet (*Trichoglossus novae-hollandiae*), and canary in the Netherlands by Zwart and Donker-Voet (1959).

Etiology. *Listeria monocytogenes* (Murray et al., 1926) Pirie, 1910, is a small Gram-positive rod (Fig. 15.1). Spores are not formed. It is motile, and when grown at 37°C. has a characteristic tumbling movement. This temperature is not so conducive to flagellum production, however, as is room temperature. The organism is a facultative aerobe. On nutrient and liver agar, circular smooth colonies are formed, which are bluish by transmitted light and milk-white by reflected light. After several days' growth on liver

agar the colonies become very viscid. A clear zone of hemolysis is formed around colonies on blood agar. With some strains, hemolysis may not occur on initial isolation but appears after several transfers. Gelatin is not liquefied; indol, acetyl methyl carbinol, and hydrogen sulfide are not formed; and nitrates are not reduced. In a study of the biochemical characteristics of 50 strains of Listeria, Harvey and Faber (1941) found that acid is produced from dextrose, levulose, galactose, maltose, mannose, rhamnose, trehalose, dextrin, and salicin; that lactose, glycerol, sucrose, arabinose, xylose, mannitol, sorbitol, and starch may or may not be fermented; and that acid is not produced from dulcitol, inositol, raffinose, glycogen, and inulin. In the writer's experience, sucrose may not be fermented on first isolation, but after several transfers on artificial culture media, this sugar is usually readily fermented. Dextrose, rhamnose, and salicin are usually fermented rapidly, while the other carbohydrates are usually fermented more slowly. Van Dorssen and Jansen (1951) gave the cultural characteristics of 25 strains isolated in the Netherlands.

Although it may grow quite lightly on initial isolation, after several transplants Listeria grows rather heavily both at 37°C. and at room temperature.

Jones and Woodbine (1961) have reviewed the cultural and other microbiologic characters of *L. monocytogenes*. Füzi and Pillis (1962) differentiated it from Erysipelothrix; Listeria was relatively sensitive to sodium azide and crystal violet, but insensitive to "Mavekal" (disodium hexadecyl disulfonate).

Several serologic studies have been carried out on Listeria. Using the agglutination test, Paterson (1940) recognized four serologic types, while Drew (1916) found two groups with the precipitin test. Jones and Woodbine (1961) reviewed the serologic typing of *L. monocytogenes*. Metzger and Smith (1962) discussed its serologic typing by gel diffusion using thermostable antigens. Njoku-Obi (1962) described an antigen fixation test for serologic diagnosis.

Rudolph and Grässer (1963) used antisera labelled with fluorescent dyes in typing. Sword and Pickett (1961) studied phage typing and developed a system of classification including 8 phage types.

Symptoms. Apparently few clinical symptoms occur in listeriosis in chickens. Paterson (1937) reported that the adult birds died suddenly, while a slow wasting was evident in young naturally affected chickens. The encephalitic symptoms which are characteristic of listeriosis in many mammals have seldom been observed in naturally affected birds, although they have been reported in geese and turkeys.

Mortality in the individual flock may vary within wide limits. Generally only sporadic cases appear, but heavy losses may also occur. Paterson, for example, reported that in one flock 120 out of 200 pullets died over a 3-month period; in another, 191 out of 424 pullets and cockerels died; and in a third flock 8 out of 24 died. In the outbreak described by van der Schaaf and de Jong (1951), 8 of 30 canaries in an aviary died.

Listeriosis has often been found in association with some other disease and may often be secondary to it. Among concurrent diseases and parasites which have been reported are pullorum disease, salmonellosis, fowl pest, lymphomatosis, Newcastle disease, coryza, coccidiosis, heavy tapeworm (*Davainea proglottina* or *Raillietina*) or *Ascaridia galli* infections, heavy mite (*Dermanyssus gallinae*) infestations, ovarian tumor, lowered resistance due to inbreeding, or hatching of imported eggs (Gray, 1958). Stress is apparently an important factor in bringing on attacks of listeriosis.

Observations made so far appear to indicate that young birds are considerably more susceptible to the disease than are adults, although these, too, may die.

Pathology. Listeria ordinarily causes a septicemia in birds. The most striking lesions observed on necropsy of both naturally and experimentally infected chickens are massive necrosis of the heart

FIG. 15.2 — Myocardial necrosis in chickens following intravenous inoculation of Listeria. (Upper left, normal.)

muscle (Fig. 15.2), although this is not an invariable finding. Pericarditis may also be present, and there may be a large amount of fluid in the pericardial cavity.

The most common lesions are necrotic foci in the liver and generalized edema. The liver may be enlarged, congested, and friable, and the spleen may be enlarged and congested. Fibrinous peritonitis and enteritis have also been reported.

The specific name *monocytogenes* was given to Listeria because of the increase in percentage of monocytes in the circulating blood of naturally affected rabbits and guinea pigs. Seastone found that a similar monocytic response is elicited in chickens.

Diagnosis. Listeria septicemia can be diagnosed by isolation of the causative microorganism on artificial culture media. In contrast to the domestic mammals, in which Listeria is often confined to the central nervous system, the organism can be isolated from the abdominal organs

Botulism

Botulism (limberneck, *bulbar paralysis*) is a disease which may affect not only chickens and other domestic birds, but also man and the domestic mammals. It is a type of food poisoning which results from ingestion of spoiled foods in which the bacterium, *Clostridium botulinum*, has been growing and producing toxins. Other bacteria which cause food poisoning in man, such as staphylococci, have not been recognized as a cause of the same condition in domestic animals.

The earliest report of botulism as the cause of so called limberneck in chickens was made in the United States by Dickson (1917, 1918). Spoiled canned corn, green beans, and apricots were found to have caused outbreaks in four flocks; in three of these cases, humans also died as a result of eating the same food. Hart (1920), Wilkins and Dutcher (1920), Graham and Schwarze (1921), Doyle (1923), Graham and Boughton (1923), and McLachlan and Newton (1952) also reported outbreaks of botulism in chickens. Van Heelsbergen (1929) observed symptoms of limberneck in Holland. The disease also occurs in other species of birds. Among others, Graham and Boughton (1923), Theiler (1927), Dadot (1945), Szyfres et al. (1948), and Gunning (1950) reported it in ducks; Martinaglia (1937) and Gunning (1950) in geese; Coburn and Quortrup (1938a) in turkeys; Palmer and Baker (1922), and Dobberstein

and Piening (1933) in swans; Dinter and Kull (1954), Vadlamudi et al. (1959), and Lee et al. (1962) in game farm pheasants, and Theiler (1927) in the ostrich. It has also been described in numerous species of wild waterfowl, in which it is an important cause of death. An interesting exception reported by Kalmbach (1939) is the vulture. This bird, which lives on decaying carcasses, is tremendously resistant to *Clostridium botulinum* toxins, withstanding as much as 300,000 guinea pig minimum lethal doses. This is a tolerance to 0.04 ml. toxin injected per gram of body weight.

Etiology. Botulism is caused by the toxins which are a metabolic product of the growth of *Clostridium botulinum*. Some fifteen subtypes of this species have been described by Meyer and Gunnison (1929a, b, c, d) on the basis of toxicity, agglutination, and fermentation reactions. Of these, *Clostridium botulinum* Type A and *Cl. botulinum* Type C are the most common causes of botulism in domestic birds. Hazen (1942) reported that a strain of *Cl. botulinum* Type E isolated from canned sprats was not toxic for chickens, but that a strain of the same type isolated from smoked salmon was.

Clostridium botulinum is an anaerobic, Gram-positive, sporeforming, large rod. It is widely dispersed in the soil and enters food as a contaminant. The mere presence of the organism, however, is in-

sufficient to cause disease or to be of diagnostic significance. Only when the organism has grown, multiplied, and produced toxins does the food become dangerous. Since growth requires anaerobic conditions, canned foods furnish an excellent culture medium. Their improper sterilization at the time of canning may result in spoilage due to *Clostridium botulinum* or other organisms. It has been noted that certain foods are less liable to spoilage than others. Those which are acid, such as cherries and other acid fruits, are unfavorable for the growth of Clostridium, while canned vegetables, such as corn and green beans, are very favorable. Hence more cases of botulism are associated with the latter type of food.

Botulism can result from consumption of carcasses of birds which have died of the disease, and also of the maggots of the blue-bottle fly, *Lucilia caesar*, from spoiled meat. The toxin formed in the meat by Clostridium is ingested by the maggots, rendering them extremely poisonous. Wilkins and Dutcher (1920) reported the toxic character of *Lucilia* larvae, but were unable to produce limberneck in chickens with the larvae of *Calliphora vomitoria* or *Musca domestica*. In an outbreak of botulism on a pheasant farm in which 4,000 birds died in two weeks, Lee et al. (1962) found *Cl. botulinum* Type C toxin in *Lucilia illustris* larvae from pheasant carcasses and feed wastes and also in adult flies. One gram of larvae contained 180,000 mouse LD_{50}'s, and pheasants died after eating eight or more third instar larvae.

A number of carbohydrates are fermented with the production of acid and gas. Different strains and types may vary in the specific carbohydrates which they attack. In milk, Type A produces slight acidity and a slow curdling precipitate, followed by digestion and darkening. Type C produces a slowly increasing acidity, without coagulation or digestion. Type A blackens and digests meat and brain media, causing an odor of putrefaction, while Type C does not. Both types liquefy gelatin, but Type A also

liquefies coagulated albumin, while Type C does not. Growth is in the form of compact, rather lenticular discs, which may later become fluffy.

Symptoms. Outbreaks of botulism are usually traceable to the feeding of spoiled canned food, decomposed meat or vegetables, or spoiled grain. Feed contaminated by feces of affected birds, the bodies of birds which have died of the disease, or the maggots of certain flies living in such carcasses may contain enough toxin to cause the disease.

Symptoms may appear within a few hours to a day or two after the spoiled food is eaten. The most common symptom is paralysis. The legs and wing muscles are usually the first affected. The birds become unable to walk, and their wings rest on the ground. If the neck muscles are affected, the head hangs limp. This symptom is responsible for the name "limberneck." In the early stages of botulism in poultry, the eyes are dull and partly closed. The chickens are inactive and show symptoms of weakness and unsteadiness when they move. The feathers are ruffled, and the birds refuse to eat.

In mild cases the leg weakness and drowsiness may disappear, and the affected birds recover in 2 or 3 days. In

FIG. 15.3 — Chicken affected with botulism.

severe cases, however, death may occur in a few hours. Fatally affected birds lie in a profound coma, appearing lifeless, for several hours before death (Fig. 15.3). In the advanced stages a broken quivering of the feathers may be observed, and in some cases large numbers of feathers are shed. Looseness of the feathers is often seen in botulism. Soft, pasty feces or even diarrhea may be observed in some cases. The severity of the symptoms and the prognosis depend on the amount of toxin ingested.

Gross pathology. Few lesions are seen at necropsy. A slight catarrhal enteritis may be present, or small but intense inflamed hemorrhagic areas may sometimes be observed. Portions of the intestine may be dilated or distended. Other gross changes are usually lacking.

Pathogenesis. As stated above, all birds which have ingested C. botulinum toxin do not die of the intoxication. The prognosis depends primarily on the amount which has been eaten. However, this toxin is one of the most powerful poisons known. Bengston (1924) found that the minimum lethal dose for guinea pigs was 0.00012 mg. per kg. when administered subcutaneously. This may be compared with the minimum lethal dose of cobra venom under similar conditions, 0.002 mg. per kg., and with that of the alkaloid aconitine, 0.06 mg. per kg.

Although it is relatively heat-stable, botulinum toxin may be destroyed by sufficient boiling. The concentration of toxin and perhaps other factors may, however, markedly affect the time necessary for its destruction. For instance, Schoenholz and Meyer (1924) found that botulinum toxin was destroyed in 6 minutes at 80° C., but that the toxin in spoiled vegetables was much more resistant due to its high concentration and to slow heat penetration.

Western duck sickness. For many years a disease of wild ducks and other water birds has been known to occur in the western part of the United States. It was studied by Wetmore (1918), who concluded that it was due to alkali poison-

ing. More recently, however, it was shown by Kalmbach (1930) and Giltner and Couch (1930) that western duck sickness is botulism.

This disease is responsible for a tremendous number of deaths among wild waterfowl. Indeed, Kalmbach (1935a, b) considers it one of the most important causes of mortality among these birds. It has been estimated that a million birds died at Malheur Lake in eastern Oregon in 1925, one to three million at Great Salt Lake in 1929, and a quarter of a million at the northern end of Great Salt Lake in 1932. In 1910 the greatest recorded epidemic occurred in the western states, causing the death of hundreds of thousands of birds. Kalmbach (1935a) states that in recent years the epidemics have increased in frequency and that the range of the disease has also increased. Kalmbach and Gunderson (1934) list outbreaks as having occurred in Alberta and Saskatchewan in Canada; Oregon, California, Nevada, Arizona, New Mexico, Texas, Utah, Idaho, Montana, Kansas, Nebraska, North Dakota, South Dakota, and Minnesota in the United States; and Mexico. Reference should be made to their paper for a comprehensive discussion of the disease. It has since been reported in Australia by Pullar (1933, 1934), Rose (1934), and Farleigh (1949); in Alberta, Canada, by Shaw and Simpson (1936); and at Tulare Lake, California, by McLean (1946). It has also been studied by Gunnison and Coleman (1932) and Coburn and Quortrup (1938b). An interesting account of the disease together with the measures which are being taken to combat it at Tule and Lower Klamath Lakes in California is given by McLeod (1950).

According to Kalmbach and Gunderson, 69 species of birds belonging to 21 families are known to have been affected with western duck sickness. Among these are herons, geese, ducks, hawks, sandpipers, gulls, and blackbirds. Domestic birds may also die if given access to areas in which the disease is present.

Western duck sickness is caused by *Clostridium botulinum* Type C. This organism and its toxins have been isolated from the livers of affected birds, mud, decaying vegetation, various fly larvae, and from dead fish, dead grasshoppers, and grain lying in the water. Outbreaks are associated with a number of factors, among them being prevalence of organic matter, a slight alkalinity (pH 7.5 to 9) which favors growth and toxin production, and a high temperature (37° C. optimum). The incidence of the disease is closely correlated with shallow stagnant water and mud flats. Quortrup and Holt (1941) showed that anaerobic conditions favorable for the growth of the organism are produced by decaying vegetable matter, such as aquatic plants killed by evaporation or terrestrial plants killed by flooding. They reported that potential toxin-producing areas could be detected by determining the pH and oxygen content of the water.

The possibility that *Pseudomonas aeruginosa* might be a factor in the production of botulinus toxin in these areas was suggested by Quortrup and Sudheimer (1943a). They isolated this organism frequently from the water of duck marshes and from wild duck intestines. *Ps. aeruginosa* utilizes oxygen and produces an alkaline medium, and these investigators showed that when it is grown together with *Cl. botulinum*, an increased amount of botulinus toxin is produced.

Diagnosis. Diagnosis of botulism in domestic birds can be made on the basis of the paralytic symptoms, loose feathers, usual absence of marked gross lesions, and history of eating spoiled food, decaying carcasses, etc. Paralysis of the nictitating membrane of the eye occurs frequently, although it is not pathognomonic. Demonstration of the toxins in the digestive tract by feeding or inoculation of experimental animals may also be resorted to. According to Quortrup and Sudheimer (1943b) the toxin is present in such an amount in the blood of affected wild ducks that it can be detected by inoculating mice in-

traperitoneally with 1 ml. of serum. Mice immunized against the toxin fail to show symptoms, while nonimmunized mice may die. The organism itself can be recovered by the use of anaerobic culture media. However, it must be borne in mind that isolation of *Clostridium botulinum* from the intestinal tract does not necessarily predicate a diagnosis of botulism, since this bacterium is commonly found in soil and may be isolated from the alimentary canal of healthy, normal birds or mammals.

Among common media utilized in the cultivation of Clostridium are meat mash, brain mash, deep tubes of liver agar, and thioglycollate broth. All these media should be brought to the boiling point and allowed to cool immediately before inoculation.

Therapy and prophylaxis. Prevention of botulism in poultry depends primarily on feeding a wholesome ration. The feeding to chickens of spoiled canned foods, tainted meats, or decomposed vegetables should be avoided, and the danger to fowls of putrefying carcasses should be recognized.

The bodies of chickens which have died of any disease are a source of danger and should be destroyed by burning. Since the droppings of affected birds contain toxin, sick birds should be isolated and their droppings removed to fields that cannot be reached by poultry.

Laxatives such as castor oil or Epsom salt are of value in the treatment of exposed birds which have not yet shown symptoms of the disease. These agents can be mixed with bran in the form of a wet mash. Mildly affected chickens which cannot eat may be dosed individually with one-half ounce of castor oil. One pound of Epsom salt for each 75 to 100 chickens may be mixed in the feed for flock treatment. All other feed should be withheld, and the treatment repeated until the digestive tract is empty. The recovery of affected birds will be aided if they are kept in a cool, shady place.

Injection of antitoxin is of value in

human botulism, and Brandly (1957) found that an aluminum hydroxide-adsorbed botulinus antitoxin gave good protection to pheasants against botulism. Boroff and Reilly (1959) immunized pheasants and ducks with two injections 3 or 4 weeks apart of a mixture of *Cl. botulinum* Type C toxoid and Freund's incomplete adjuvant. Quortrup and Sudheimer (1942) reported that the majority of birds affected with western duck sickness would recover if treated with Type C botulinus antitoxin. At the Tule Lake Refuge, according to McLeod (1950), thousands of wild ducks were treated intraperitoneally with antitoxin, large ducks receiving 4 ml. and small ones 2 ml. Seventy per cent of the

treated birds recovered. The average cost of antitoxin was estimated to be 11 cents a duck. However, Rosen and Bischoff (1953) stated that such duck rescue work costs three to five dollars per bird rescued. They used a different and much more successful approach during an outbreak of botulism in the Tulare Lake Basin in 1952. By herding the ducks away from dangerous areas by plane, air-thrust boat, and through the use of pyrotechnics, by pumping operations carried out by the area farmers, and by distributing feed in safe areas, they reduced the mortality among 2 million ducks to 1 per cent as compared with an expected mortality of 20 per cent.

Erysipelas
(Gefluegelrotlauf)

A septicemia associated with *Erysipelothrix insidiosa*, the causative agent of swine erysipelas, has been reported in many species of birds. Jarosch (1905) was the first to recognize this disease in birds, isolating the organism from a turkey. Subsequently the disease has been found to occur also in the chicken, duck, pigeon, pheasant, quail, peacock, and a number of wild birds. It is found throughout the world. Since Jarosch's initial paper, erysipelas has been described in turkeys by

Eber (1921), Beaudette and Hudson (1936), Madsen (1937), Hoffman and Hinshaw (1938), Van Roekel et al. (1938), Rosenwald and Dickinson (1939, 1941), Rosenwald (1940), Schlotthauer and Thompson (1940), Lindenmayer and Hamilton (1942), Burnett and Hofstad (1943), Lindenmayer (1943), Jungherr and Gifford (1944), Stiles (1946), Moore (1947), Brown et al. (1949), Blaxland et al. (1949), Bivins (1949), Hudson (1949), DeLay and Koch (1950), Peterson and

Hymas (1950), Dunne et al. (1951), Moore (1951), Byrne et al. (1952), Hudson et al. (1952), Bivins et al. (1955), Elliott (1956), and Raines and Winkel (1956).

Hausser (1909) first described the disease in the chicken. It has since been reported in this bird by Schipp (1910), Broll (1911), Pfaff (1921), Reinhardt (1924), Scholl and Jacquart (1926), van Heelsbergen (1929), Schmidt-Hoensdorf (1931), Sparapani (1938), Breed (1943), Evans and Narotsky (1954), Juslin and Stenberg (1954), Bivins et al. (1955), and Hall (1963). Poels (1919) first encountered erysipelas septicemia in ducks, and this finding was confirmed by Eber (1921), Scholl and Jacquart (1926), Werner (1932), Horstmann (1938), Graham et al. (1939), White and Henley (1942), Doria (1943), Hudson (1949), Hudson et al. (1952), Zeiger (1952), Galli (1953), Dougherty and Bruner (1954), Engel and van der Maas (1955), Valentin et al. (1956–57), Murase et al. (1959), and Nikolić and Sepic (1961).

It was reported in a wild mallard (Anas pl. platyrhynchos) by Bourgeois (1944). The disease was recognized in the pigeon by Poels (1919) and de Mendonça Machado (1945); in the quail by Jármai (1920), Waller (1939), and van Dorssen and Donkervoet (1953); in the pheasant by Vianello (1898), Morgan (according to Waller, 1939), Szabó (1943), Hudson et al. (1952), Rossi and Pini (1953), Raines and Winkel (1956), Valentin et al. (1956–57), and Trbić and Tadić (1959); in the peacock by Greener (1959); in the goose by Linsert (1914); in the green finch by de la Villa (1934); in the ring-necked parakeet (Palaeornis torquata) by Urbain et al. (1945); in the white stork (Ciconia ciconia) and herring gull (Larus argentatus) by Christiansen (1919); and in birds in zoological gardens by Jármai (1920) and Schmidt-Hoensdorf (1931). Van Bemmel et al. (1960) found it in fruit pigeons (Ducula sp.) and fisheating birds such as the crowned crane (Balearica pavonina) and Porphyrio sp. in the Rotterdam zoo.

The same organism, or a very similar one, has also been found in the sheep, ox,

horse, dog, mink, guinea pig, mouse, rat, chipmunk, porpoise, several species of fish, and man (Van Es and McGrath, 1936; Stiles, 1944; Drake and Hall, 1947; Grey, 1947a; Connell, 1954; Seibold and Neal, 1956).

Etiology. The etiologic agent, *Erysipelothrix insidiosa* (Syn., *E. rhusiopathiae*), can be isolated culturally from many of the organs of affected birds. Since the disease is a septicemia, the heart blood, liver, pericardial fluid, and pathologic accumulations of fluid usually contain large numbers of the organisms. The bacterium has also been isolated from diphtheritic membranes on the pharyngeal and nasal mucosae. While isolation may be accomplished on plain nutrient agar, it is more uniformly successful if blood or serum is added to the medium.

E. insidiosa on first isolation is a Gram-positive rod, but after continued transfer on artificial culture media it may become Gram-negative. In the animal body and when first isolated, the organisms may be relatively short ($1-2\mu$ long), but on cultivation they ordinarily are in the form of slender filaments $4-15\mu$ long (Fig. 15.4). Branching of the filaments has been described. The organism forms no spores and is nonmotile. The colonies are round and translucent, usually about 1 mm. in diameter. On first isolation they

FIG. 15.4—*Erysipelothrix insidiosa*, agar culture. X2,000. (From Nowak: Documenta Microbiologica, courtesy Gustav Fischer.)

are smooth, but, on continued transfer, larger, rough colonies may appear. Gelatin is not liquefied, but a typical "test tube brush" growth occurs along the line of the stab. Litmus milk may be slightly acidified. A narrow zone of green hemolysis forms on blood agar. Neither indol nor acetyl methyl carbinol is formed, but hydrogen sulfide is produced. Gas is not formed from carbohydrate media. According to Karlson (1938), acid is formed in dextrose, lactose, galactose, and levulose, while mannose and cellobiose are fermented late, and no acid is formed from arabinose, xylose, rhamnose, maltose, melibiose, sucrose, trehalose, raffinose, melezitose, dextrin, starch, inulin, amygdalin, salicin, glycerol, erythritol, adonitol, mannitol, sorbitol, dulcitol, or inositol. Maximum growth occurs at a pH of 7.6 at 37.5° C. Füzi and Pillis (1962) differentiated between *E. insidiosa* and *Listeria monocytogenes*; the former is relatively resistant to crystal violet and sodium azide, but is relatively sensitive to "Mavekal" (disodium hexadecyl disulfonate) *in vitro*. Further information on the bacteriology of the organism is given by Woodbine (1950), Byrne *et al.* (1952), and Juslin and Stenberg (1954).

Symptoms and pathology. *Turkey.* Erysipelas usually affects poults from four to seven months of age, although Rosenwald (1940) reported it in a 7-day-old poult. It usually appears in the fall, most outbreaks which have been reported having occurred in September, October, and November. Losses may be fairly heavy, mortalities of from 2½ to 25 per cent having been reported in different flocks. An interesting characteristic of this disease is the fact that male birds are apparently much more susceptible than females. This differential sex incidence has been reported by a number of writers. Madsen (1937), for instance, stated that out of 1,200, 325 turkeys which died in a flock of 1,200, only 25 were females, while Rosenwald and Dickinson (1941) reported that 82.1 per cent of the turkeys affected in outbreaks in 16 flocks were males.

Symptoms include general weakness and listlessness, inappetence, and sometimes a yellowish or greenish diarrhea. Affected birds stand or crouch with lowered head, drooping wings and tail, and ruffled feathers. The skin and wattles may be cyanotic. Dyspnea and an ulcerated nasal mucosa may be present. Rosenwald and Dickinson (1941) consider the most pathognomonic lesion to be a turgid, reddish-purple caruncle.

At necropsy the most characteristic lesions are petechial and diffuse hemorrhages in many of the tissues and organs. They have been reported in the abdominal, pectoral, and femoral muscles, fascia, peritracheal tissues, pleura, peritoneum, pericardium, heart, lungs, spleen, and small intestine. The liver is enlarged, congested, and often friable or mottled. In some cases necrotic foci may be present in this organ. The spleen is usually enlarged, congested, and friable, and hemorrhages or necrotic foci may be observed. The kidneys may be enlarged and congested. The lungs may be congested or brownish in color. A catarrhal exudate which may be sanguineous is present in the intestine, and the intestinal mucosa may be inflamed, edematous, hemorrhagic, or even necrotic. The mesenteric and other blood vessels are often engorged. A nasopharyngeal catarrh has been observed in some cases. Inflammation of the mucosa of the proventriculus has been reported, and a swollen joint was noted in one case by Beaudette and Hudson (1936). On the other hand, in the cases in week-old poults reported by Rosenwald (1940), characteristic lesions were absent on necropsy.

Peterson and Hymas (1950) reported a chronic cutaneous form of the disease in a single male breeder turkey from a Washington state flock. The breast was covered by a large, thick, leathery brown wheal, and similar lesions were present in the skin on other parts of the body. Erysipelothrix was isolated from the necrotic tissue, but not from the internal organs, which appeared normal. For further in-

formation on the disease in turkeys, see the discussion in Chapter 11 of this book.

Chicken. Symptoms of lassitude, inappetence, and diarrhea may be present in the chicken. The pathological anatomical changes induced in this bird by *Erysipelothrix insidiosa* are similar to those in the turkey, but are usually not so marked. The report by Sparapani (1938) of a paralysis of chickens due to lumbar meningitis caused by *Erysipelothrix insidiosa* is of interest.

Duck. Ducklings are susceptible to erysipelas. Losses may be quite high. In one flock of 46,000, Graham *et al.* (1939) reported a loss of almost 25 per cent. In the duck the gross pathologic lesions are similar to those in the turkey and chicken. A serofibrinous exudate may be present in the air sacs, and the lungs are often congested. The liver is often enlarged, friable, mottled, and may contain numerous yellowish pin-point foci. The spleen is usually congested, enlarged, and soft. Petechial hemorrhages may be present in the heart. Areas of congestion are often found in the intestine, and catarrhal enteritis may be observed. Dark, congested areas in the webs of the feet, and chronic enlargement of the femorotibial articulations have also been reported. Congestion may be found in many of the organs, and petechiation of the muscles may also occur.

The symptoms and lesions caused by *Erysipelothrix insidiosa* in other species of birds are similar to those described above.

Pathogenesis. The pathogenicity of *Erysipelothrix insidiosa* for pigeons is well established. Indeed, in some laboratories, inoculation of these birds is a routine procedure for the diagnosis of swine erysipelas. While the turkey is quite susceptible to the disease, its susceptibility is increased by other infectious diseases, malnutrition, or any condition which lowers the bird's vitality. Among predisposing factors are confinement, overcrowding, damp or inclement weather, drafts, sudden temperature changes, and poor sanitation. Of interest in this connection is the report of Marinelli (1928)

that the feeding of polished rice lowers the resistance of pigeons to Erysipelothrix. It is noteworthy that most of the outbreaks of erysipelas reported have occurred in the fall and winter months.

While the pathogenicity of *E. insidiosa* is about the same for the duck as for the turkey, it is definitely lower for the chicken. Most of the cases in this species have been sporadic rather than epidemic in nature, and other diseases such as pasteurellosis, tuberculosis, and leukosis have often been present also. Experimental inoculations of the organism by a number of workers give further confirmation of the relatively greater resistance to infection of the chicken.

Diagnosis. While extensive petechiation is quite characteristic of erysipelas in birds, reliance cannot be placed upon this lesion alone in arriving at a diagnosis. A positive diagnosis can be made only by isolating the causative microorganism from the tissues of affected birds by cultural methods, and identifying it. For best results, cultures of heart blood, liver, or other organs should be seeded on blood or serum agar.

A presumptive diagnosis can often be made by examination of thin blood smears stained by Gram's method. The organisms may be abundant in the heart blood or spleen. Filamentous forms are usually absent in the animal tissues.

A serological test might be helpful, since it has been reported by a number of workers that high agglutinin titers may result from natural or experimental infection.

Epidemiology. Erysipelothrix is generally considered able to live for a long time in the soil, so that infected premises are a source of infection. However, Doyle (1960) reviewed the evidence for this belief and concluded that there is no evidence that *E. insidiosa* can multiply in the soil, that the length of time it can survive in the soil is no greater than that of many other non-sporeforming pathogenic bacteria, and that the soil is therefore not the most important source of infection. In this connec-

tion, Gurova (1959) found that *E. insidiosa* would survive only 21 to 30 days in damp, nonsterilized, Ukrainian black-earth type soil in petri dishes, although it survived much longer in sterilized soil.

E. insidiosa has been recovered from fish meal (Grenci, 1943), so mixed feeds may also be a source. However, Kubiš (1942) reported that the organism was killed in the small intestine after ingestion by the pigeon. Infected swine, sheep, rats, and fish are reservoirs of infection for birds.

It has been suggested that the organism enters the body through scratches or abrasions in the skin. In addition, Wellmann (1950) found that *E. insidiosa* could be transmitted mechanically from sick mice to pigeons by the stable fly, horsefly, mosquitoes, and other biting flies.

Erysipelothrix is infectious for man; infections in persons who have handled or performed necropsies on sick birds have been reported by Bivins (1949), Narotsky and Hawley (1949), Dunne *et al.* (1951), Hudson *et al.* (1952), and Evans and Narotsky (1954).

Therapy. Penicillin, and particularly its longer-lasting derivatives such as procaine penicillin or benzathine penicillin, have been used with success in treating affected turkeys, pigeons, and pheasants, usually by intramuscular injection (Heilman and Herrell, 1944; Van Es *et al.*, 1945; Gifford and Jungherr, 1946; Grey, 1947a, 1947b; Brown *et al.*, 1949; Prier and Alberts, 1950; DeLay and Koch, 1950; Dunne *et al.*, 1951; Moynihan and Stovell, 1954; Smith, 1956; Jerstad and Johns, 1956; Raines and Winkel, 1956). In addition, Elliott (1956) and Boyer and Brown (1957) reported that administration of procaine penicillin in the feed was effective in controlling the outbreaks of erysipelas in turkeys. Boyer and Brown (1957) used 800 gm. per ton of feed, while Elliott (1956) used 200 gm. per ton the first week, 120 gm. per ton the second week, and 64 gm. per ton the third week. However, Raines and Winkel (1956) reported an outbreak in turkeys due to a penicillin-resistant strain

of Erysipelothrix which was sensitive to dihydrostreptomycin.

The tetracycline group antibiotics are also quite active (Prier and Alberts, 1950; Moynihan and Stovell, 1954; Smith, 1956). Boyer and Brown (1957) found that 325–600 gm. of chlortetracycline per ton of feed reduced mortality in affected turkeys. Orlandella (1955) cured experimentally infected pigeons with erythromycin administered either orally or subcutaneously.

Streptomycin is much less effective than penicillin (Woodbine with Cheeseman, 1947; Grey, 1947c), but Dunne *et al.* (1951) found that dihydrostreptomycin was effective in treating turkeys, and Raines and Winkel (1956) used it successfully against a penicillin-resistant strain of Erysipelothrix.

The sulfonamides are apparently valueless for treating *E. insidiosa* infections (Konst, 1945; Frei and Jezierski, 1945; Woodbine, 1946, 1950) as is furazolidone (Smith, 1956; Jerstad and Johns, 1957). Further information on the chemotherapy of Erysipelothrix is given by Woodbine (1950), Moynihan and Stovell (1954), and Smith (1956).

Immunization. A formalin-killed, aluminum hydroxide-adsorbed *E. insidiosa* bacterin has been used successfully by a number of workers to immunize turkeys (Adler and Spencer, 1952; Dickinson *et al.*, 1953; Jerstad and Johns, 1954a, 1954b; Boyer and Brown, 1956; Cooper *et al.*, 1954, 1957; Boyer and Brown, 1957). This immunity is not great enough to protect all birds against experimental challenge, but it has been found of practical value under field conditions. It can be used in conjunction with penicillin treatment of sick birds at the beginning of an outbreak to control losses. Mitrovic *et al.* (1961) found that a concentrated, formolized, adsorbed vaccine made from variant smooth strains H4 and H7 of *E. insidiosa* protected turkeys better than a commercial vaccine made from five rough strains.

In a preliminary study, Osebold *et al.* (1950) found that vaccination with a live, avirulent culture of *E. insidiosa* pro-

tected turkeys against challenge with a virulent strain 12 weeks later. Peterson and Hymas (1952) immunized turkeys by simultaneous injection of a live, attenuated culture and antiserum.

Treatment with antiserum alone may be of some value, but only if it is administered very early or before clinical symptoms appear. Sparapani (1938) reported the successful use of swine erysipelas antiserum in chickens, as did White and Henley (1942) in ducks, Breed (1943) in chickens, and Grey (1947b) in turkeys, if

it was given early enough. On the other hand, attempts by Graham et al. (1939) to protect ducklings on contaminated premises by the use of antisera and bacterins were unsuccessful. Brown et al. (1949) gave antiserum to an infected flock of turkeys with equivocal results. Rosenwald and Dickinson (1941) reported that the use of commercial swine erysipelas antiserum was impractical in the treatment or prevention of the disease in turkeys.

Goose Influenza
(Septicaemia anserum exsudativa)

Goose influenza was first described in some detail by Riemer (1904) as the cause of a fatal disease of geese in Germany, and a specific bacterium was isolated from the affected birds. A similar microorganism was found in geese by Bugge (1908). This disease was later encountered in several German provinces by a number of investigators (Gerriets, 1953). Their data indicate that the disease was probably introduced into Germany by Russian and Polish geese. The disease of geese described by M'Fadyean (1902) in England was probably goose influenza. The hemorrhagic septicemia observed by Fiorentini (1896) in geese and swans was, however, due to a different organism, a bipolar staining, motile coliform rod, pathogenic for chickens, pigeons, rabbits, guinea pigs, geese, and ducks. The influenza bacterium, on the other hand, is pathogenic only for geese. Although this disease has not been reported in North America, the writer

(unpublished data) isolated an organism from a young goose in Illinois which was similar in preliminary tests to the causative agent of goose influenza.

Etiology. The organism causing goose influenza appears in the animal body as a small rod, frequently resembling a diplococcus. It varies in size from 0.5 to 1.5 by 0.5μ. It can always be found in large numbers in the heart blood, pericardial fluid, and fibrinous exudates. It is Gramnegative, forms no spores, and is nonmotile. While it can be rather easily isolated from an affected bird on plain nutrient agar, a medium containing hemoglobin is necessary for further transfers. Once adapted to artificial culture media, however, it will grow on plain agar.

Small, white, circular colonies are formed on gelatin plates, while in gelatin stabs a slight infundibuliform liquefaction occurs which becomes complete in several weeks. On nutrient agar, circular,

transparent, smooth, homogeneous, slightly viscid colonies are formed. They are grayish-white (bluish by transmitted light) at first, but become brownish-yellow with age. In broth a uniform turbidity is produced, and a slight sediment is formed after a few days. A pellicle may or may not be formed. Indol is usually not formed. Litmus milk is unchanged. Slight acid may be produced from dextrose but not from lactose. Hydrogen sulfide is formed. On coagulated blood serum, a yellowish-white growth appears, and the medium later becomes brownish and still later is liquefied. No growth occurs on Drigalski-Conradi or Endo media. The optimum temperature is about 37.5° C. No growth occurs below 15°, while an exposure to 56° C. for 5 minutes kills the organisms. Cultures are viable only a relatively short time.

The systematic position of this organism has varied with different authorities. Riemer (1904) named it *Bacillus septicaemiae anserum exudativae*, and it also been assigned to the genera *Shigella* (Bergey *et al.*, 1939, Smith, 1948) and *Hemophilus* (Frosch and Bierbaum, 1909; Löffler, 1910; Schlüter, 1936; Gerriets, 1953). However, Breed *et al.* (1957) called it *Pasteurella septicaemiae*, and this name is being used herein.

Symptoms. Both young and old geese are susceptible to the disease, while ducks, chickens, and turkeys are not affected. The disease generally appears in May and the first half of June, sometimes reappearing in the latter part of August and September. At the beginning of an outbreak, a few cases and some deaths are observed, but later a high percentage of the flock may become affected. At first the disease is found in the young geese, but as the epidemic progresses older birds are also affected. The mortality in young birds is especially high, often 70 to 90 per cent. The disease usually disappears from the flock in two to four weeks.

Few affected birds survive, and these generally exhibit paralysis or leg weakness for some time.

The first striking symptom is a decrease in appetite. The birds gradually become weaker, squat with ruffled feathers, and keep apart from the rest of the flock. According to Bugge, diarrhea sets in 12 to 24 hours before death. The birds strike with their legs and head, stagger while walking, and breathe rapidly. The beak is opened wide and a snoring noise is emitted. Death may come either gradually or quite suddenly. The course of the disease is ordinarily 2 to 5 days, although sometimes the birds may die within an hour after symptoms appear.

Pathology. In this disease two postmortem pictures have been described which are in partial agreement. Riemer described an exudative septicemia, while Bugge emphasized the inflammation of the air sacs and the lung lesions. Both Riemer (1904) and Eber (1921) found at necropsy only a slender, lightly adhering film on the liver surface, fine fibrinous threads on the epicardium, and a small amount of a turbid, serous exudate in the pericardium. No other morbid changes in the organs or tissues were demonstrated. According to Bugge, the roughened surface of the air sacs is covered by a yellowish film which can be easily pulled off, and the inner surfaces are covered by thick, coherent, whitish-yellow fibrin masses frequently distributed in reticular fashion. Since these masses may continue on to the lateral and posterior borders of the lung, numerous yellow nodules from the size of a pinhead to that of a pea are visible through the healthy rosy-red lung tissue at these places. The peripheral bronchi are filled with yellowish fibrinous masses. In a few cases hemorrhages in the intestinal mucosa and enlargement of the spleen, liver, and kidneys are observed.

Pathogenicity. The organism of goose influenza is pathogenic for geese, but rabbits, gray and white rats, mice, ducks, chickens, and pigeons are not affected by it. Guinea pigs may be killed by a large inoculum of the bacteria. Cultures lose

their virulence rather rapidly if they are not passed through geese regularly.

Diagnosis. In dead geese the disease is recognized rather easily by the characteristic fibrinous inflammation of the serous membranes or of the air sacs as well as by symptoms of a general septicemia. The diagnosis is confirmed by recognition of the bacteria in stained smears from affected areas or heart blood, or by isolation and identification of the causative microorganism.

Therapy. According to Gerriets (1953),

penicillin and sulfathiazole are effective in treating this disease.

Prevention. While vaccination with an autogenous bacterin may be attempted, the main emphasis in the control of goose influenza must be placed on the application of hygienic measures. Newly acquired birds should be held under quarantine. Sick birds should be separated from the rest of the flock or slaughtered, and all carcasses should be destroyed by burning. Houses and runs should be disinfected.

Streptococcosis, Staphylococcosis, Arthritis, Coli-granuloma (Hjärre's Disease), and Colibacillosis

Avian Streptococcosis

Streptococcic infections occur sporadically in fowls. The disease has been reported in many countries of the world. It has been described as an acute septicemia of fowls (Nórgaard and Mohler, 1902; Greve, 1908; Magnusson, 1910; Hudson, 1933; Edwards, 1934; Buxton, 1952). Others have described chronic infections caused by streptococci (Dammann and Manegold, 1905; Kernkamp, 1927; Edwards and Hull, 1937). Streptococci have been isolated from an acute disease in young geese and ducklings by Hodosy (1944) from turkeys by Volkmar (1932), and from pigeons by Madej (1961).

Etiology. The most common causative agent is *Streptococcus gallinarum*. Merchant and Packer (1961) have described this organism as Gram-positive, occurring in chains of 6 to 8 cells. Long chains are found in fluid media, while diplococcoid forms occur on solid media. Some strains

have capsules. On agar, young colonies are white and gelatinous. Older colonies have bluish borders and brown centers. Beta hemolysis is observed on blood agar, and leucocidin is also produced. *Streptococcus zooepidemicus* also may be isolated occasionally from chickens (Edwards and Hull, 1937; Packer, 1951; Buxton, 1952; Agrimi, 1956; Sato *et al.*, 1960). This species can be distinguished from *Streptococcus gallinarum* by its ability to ferment sorbitol. *Streptococcus gallinarum* does not ferment this sugar. Agrimi (1956) isolated *Streptococcus faecalis* from 5 of 6 cases of acute septicemia in fowls. *S. faecalis* has been isolated from cases of bacterial endocarditis by Gross (1962).

Transmission. The disease has been reproduced with strains isolated from acute outbreaks. The route of infection in the natural disease is not known, although Hudson (1933) suggested that the organism might be introduced by way of the respiratory tract. He also mentioned that

carriers may exist after an outbreak and that these might serve to introduce the *disease into a susceptible flock.*

Pathogenicity. Chickens are the natural host, but other species, namely rabbits, pigeons, ducks, geese, turkeys, and white mice, are susceptible. Guinea pigs are resistant.

Symptoms and lesions. In acute cases death may occur without definite symptoms. Lesions consist of congestion and enlargement of the parenchymatous organs. In the chronic form, depression and debility are prominent symptoms. On necropsy there may be necrotic foci in the liver, a fibrinous exudate in the abdominal cavity, and an enteritis.

Mortality. In the flock described by

Nörgaard and Mohler (1902) the loss was *over* 90 per cent of the birds. Losses in other outbreaks mentioned were less severe, and in chronic cases the mortality was considerably less.

Diagnosis. Isolation of *Streptococcus gallinarum* or *Streptococcus zooepidemicus* constitutes a diagnosis. The organism may be isolated from the blood and parenchymatous organs, or in chronic cases from localized areas of infection.

Treatment. While there have been *no* reports of attempted treatment with the sulfonamides and antibiotics, some of these might be tried in outbreaks of streptococcosis, particularly where valuable breeding stock is involved.

Avian Staphylococcosis

Staphylococci are occasionally isolated from chronic or acute conditions of fowl. The organism has been isolated from cases of arthritis (Hole and Purchase,

1931; Jungherr, 1933; Gwatkin, 1940; Jungherr and Plastridge, 1941; Rowlands and Smith, 1945; Fahey, 1954). Staphylococci have been isolated from cases of

vesicular dermatitis (Hoffman, 1939), omphalitis (Williams and Daines, 1942), keel bursitis (Van Ness, 1946), and synovitis (Hinshaw and McNeil, 1952; and Madsen, 1942). Other reports of staphylococcic infections in fowl have been made (Lucet, 1892; Freese, 1907; Eber, 1921; Hasenkamp and Sachwch, 1914; Schlegel, 1922; Reinhardt, 1922; van Heelsbergen, 1919, 1929; Seetharaman and Sharma, 1949; Dal Santo, 1959; Sato et al., 1961). Outbreaks of "wing-tip" gangrene due to Staphylococcus aureus and Clostridium welchii Type D have been described in Italy (Rossi, 1956; Mondini and Quaglio, 1956, 1959; Zoletto, 1957). Rossi describes the acute form of the disease as a catarrhal conjunctivitis, crust formation on the skin of the back, joint lesions, and purulent panophthalmia and death in 8–10 days. Mortality was 50 per cent in 5 flocks of young chicks. Mondini and Quaglio (1959) state that osteoarthritis is a prominent feature in the majority of cases.

Etiology. The causative organism is Staphylococcus aureus. The pathogenic strains coagulate rabbit plasma, produce beta hemolysis on blood agar, ferment lactose and manitol, liquefy gelatin, and produce necrosis in the skin of rabbits.

Susceptible species. Staphylococcus aureus has been isolated from geese (Lucet, 1892; Rowlands and Smith, 1945), from pheasants (Hole and Purchase, 1931), from turkeys (Jungherr, 1933), and from chickens. Rabbits are the most susceptible of the laboratory animals (Merchant and Packer, 1961).

Transmission. Pathogenic strains of Staphylococcus aureus produce a fatal septicemia in young chicks when given intravenously. Occasionally an arthritic lesion is produced (Jungherr and Plastridge, 1941). In the natural disease it is believed that injuries serve as portals of

entry for Staphylococcus aureus. Hinshaw and McNeil (1952) could reproduce the disease in turkeys only by intravenous inoculation.

Symptoms and lesions. In the acute disease, which is fatal within several days, there are symptoms of diarrhea, depression, and joint swelling. The parenchymatous organs are found congested and swollen at necropsy. In the chronic cases the outstanding symptoms are a hobbling gait, frequent sitting or reluctance to move, enlarged joints, gradual emaciation, and finally death. The pathology is primarily an arthritis and synovitis. The tibiometatarsal joint is most frequently involved, although others may be affected. Initially there is a swelling of the affected joint, which is due to a serous inflammatory exudate. Later this exudate becomes caseous in character, and the joint swelling becomes firm.

Diagnosis. Isolation of Staphylococcus aureus from the blood stream or from affected joints of sick birds constitutes a diagnosis. The pathogenicity of the organism isolated should be determined by the coagulase test and the presence of alpha hemolysin.

Treatment and prevention. Autogenous bacterins, sulfadiazine, and sulfanilamide have not been effective (Jungherr and Plastridge, 1941; Rowlands and Smith, 1945). Broad-spectrum antibiotics were found effective in treating turkey poults suffering from arthritis (Fahey, 1954).

Since injuries may serve as atria of infection, sharp objects, such as nails, glass, and barbed wire, should be removed from the premises. Wire floors should be examined for sharp ends. When anti-pick devices must be placed on the birds, some precaution should be taken to avoid introducing infection.

Coli-granuloma (Hjärre's Disease)

A condition in chickens characterized by granulomatous lesions in the wall of the digestive tract and in the liver has been described by Hjärre and Wramby (1945). It is a fairly common disease in Sweden and is important because it can be confused with *tuberculosis*. Granulomas similar in morphology and distribution, but of unknown etiology, have been observed in the United States (Bennett *et al.*, 1951; Jungherr, 1949; Snoeyenbos, 1952). In Canada, Schofield (1947) ob-

served a disease in turkeys which he considered to be coli-granuloma. Wickware (1948), also from Canada, found the disease in chickens. Savage and Isa (1956) observed the disease in 11 cases, 10 of them being in turkeys. Hamilton and Conrad (1958) diagnosed the disease in 2 outbreaks involving 1,000 and 2,000 chickens. Mortality was 75 per cent and a mucoid *E. coli* was isolated; however, they were unable to reproduce the condition.

Etiology. Hjärre and Wramby (1945)

found a coliform bacterium as the causative agent. It is a Gram-negative, capsulated organism which forms mucoid colonies. The mucoid, M-form, of the organism may dissociate in culture into an S-form and a noncapsulated R-form. The agglutination type of the M-form corresponds with Kauffman's M-agglutination in coliform bacteria. Ulbrich (1951) studied 22 mucoid strains of *E. coli* isolated from cases of coli-granuloma in Germany and Sweden. Sixteen belonged to O group 4, four to O group 8, and two to O group 16. Six capsular (K) antigens were found among the cultures: K1, K6, K7, K8, K9, and K12. H antigen was not demonstrated among these cultures.

Pathogenicity. The disease is apparently only slightly infectious. Feeding infected material has not produced the disease. However, intramuscular injections of infected tissue suspensions or intravenous injections of pure cultures of the coliform organism have resulted in typical morphological lesions in many of the experimental chickens (Hjärre and Wramby, 1945). The bacterium is also pathogenic for white mice and rabbits.

Symptoms and lesions. Affected birds become thin and depressed. The organs most commonly involved are the ceca and liver, although granulomae may occur at

FIG. 16.2 — Longitudinal section of cecum through a granuloma. Enlarged. (Hjärre, State Vet. Med. Inst., Stockholm, Sweden.)

FIG. 16.3 — Ceca containing granulomae (Hjärre, State Vet. Med. Inst., Stockholm, Sweden.)
FIG. 16.4 — Liver from chicken with coli-granuloma. (Hjarre, State Vet. Med. Inst., Stockholm, Sweden.)

any place along the digestive tract and in the spleen and bone marrow (Hjarre and Wramby, 1945). It is common to find only isolated granulomae on the wall of the ceca (Fig. 16.2), although the lesions may involve the entire wall (Fig. 16.3). When the disease involves the liver, there is enlargement and large, irregularly shaped areas of necrosis (Fig. 16.4).

Diagnosis. Coli-granuloma may be confused with tuberculosis, although distribution of lesions, microscopic pathology, and the absence of acid-fast bacilli serve in differentiation. Old coli-granulomae cannot be distinguished from tuberculosis on the basis of morphology. In the early stages the coli-granulomae differ from tubercles in quantity, size, and appearance of giant cells (Hjärre and Wramby, 1945). Isolation of a mucoid, capsulated coliform bacterium which will reproduce the disease in experimental chickens would constitute a diagnosis.

Avian Colibacillosis

Escherichia coli frequently can be isolated from diseased fowl. It is usually considered to be a secondary invader, although it has been incriminated as the cause of death in some flocks.

A number of investigators have reported on the isolation of coliform bacteria from septicemic infections of fowl (Lignières, 1894; Martel, 1897; Claussen, 1907; Zeiss, 1914; Palmer and Baker, 1923; Davis, 1938; Twisselmann, 1939; Gurumurthi and Panduranga Rao, 1962). Some have suggested that *E. coli* can cause a septicemia if the resistance of the bird is weakened by hunger, thirst, extremes of temperature, and low vitality (Claussen, 1907; Davis, 1938). Coliform organisms have been isolated from eggs laid by hens infected with *Salmonella pullorum* (Garrard, 1946). Bueno (1940) found the coliform organisms common in the lower digestive tract of chickens. Isolations of *E. coli* are made frequently from cases of pericarditis associated with so-called air sac infection in broilers (Gross, 1956; Biddle and Cover, 1957). Gross and Siegel (1959) produced peritonitis in chickens by intraperitoneal inoculation of a pathogenic strain of *E. coli* together with sterile yolk. Edwards and Ewing (1954) studied 50 cultures of *E. coli* isolated from internal organs of fowl and found them to belong to serotype 02:K1:H5. This type was not found among 200 cultures of *E. coli* from the intestines of fowl or other animals. Gross (1956) found this serotype to produce pericarditis and air sac infection. Sojka and Carnaghan (1961) studied 797 *E. coli* strains from poultry. Over 60 per cent belonged to the serological "O" groups, 02, 078, and 01.

Reproduction of *E. coli* infection has been attempted by some investigators.

Davis (1938), using both healthy chicks and chicks of low vitality, was able to demonstrate pathogenicity of the organism for the weak chicks, but low pathogenicity for the healthy chicks. Osborne *et al.* (1946) made inoculations of several strains of *E. coli* intraperitoneally into twenty-four young chicks. The chicks sickened within 24 hours, although all but two recovered. Gross (1956) found that five serological types of *E. coli* were capable of producing pericarditis following air sac inoculation or aerosol exposure. A combination of other agents, such as *Mycoplasma gallisepticum*, increased the pathogenicity of *E. coli*.

Symptoms and lesions. In the disease described by Davis (1938) the young chicks were weak and had a pasty vent. At necropsy about 50 per cent of the chicks had enlarged livers with necrotic foci. A few of the livers were covered with a gelatinous exudate. All had unabsorbed yolks. The disease described by Claussen (1907) affecting adult chickens was similar to fowl cholera. The birds were depressed, refused to eat, and some had diarrhea. Necropsy of affected chickens revealed petechial hemorrhages and hepatic congestion.

Diagnosis. Isolation of *Escherichia coli* from the blood and parenchymatous organs of killed, sick fowl, and the elimination of other possible causes are necessary for an accurate diagnosis. Some effort should be made to determine the pathogenicity of the isolated organism for the species from which it was cultured, and if possible to have the organism typed. Sojka and Carnaghan (1961) found all strains sensitive to furazolidone. An increasing number of strains were found resistant to tetracycline.

Ulcerated Enteritis, Quail Disease

This enteric disease is primarily of importance to those engaged in rearing quail, but increasing reports of morbidity and mortality from this disease in other avian species points up the need for diagnosis and treatment.

INCIDENCE

Durant and Doll (1941) stated that the disease was reported in the common Bobwhite, the California quail, the mountain quail, the sharptail grouse, the Gambel's quail, the European partridge, the chukar partridge, the wild turkey, and the domestic fowl. Levine (1932) reported on ulcerative enteritis of epidemic proportions in ruffed grouse and transmitted the disease to quail by feeding them flies that had been permitted to feed on intestinal contents from the affected grouse. Fenstermacher and Doyle, in the report by Schillinger and Morley (1934), found ulcerative enteritis in young turkeys and indicated it could be a serious problem. Bullis and Van

Roekel (1944) reported finding ulcerative enteritis in domestic turkeys and they submitted intestines to J. E. Shillinger of the U.S.D.A. who succeeded in infecting quail with this material. Glover (1951) and Peckham (1963) observed ulcerative enteritis in pigeons. Shillinger and Morley (1934) reported observing ulcerative enteritis in young wild turkeys. They also described the disease in domestic chicks and pullets, and they infected quail with intestinal contents from these chickens. These workers were able to transmit ulcerative enteritis from quail to wild turkey poults. Peckham (1959, 1960) reported transmission of the disease to quail by oral inoculation of liver suspensions or intestinal contents from affected chickens or turkey poults. Buss *et al.* (1958) found the disease in pheasants and in wild quail taken in southern Washington. Most of the reports concerning ulcerative enteritis have originated in the United States but Harris (1961) was the first to record an outbreak of ulcerative
enteritis occurring in quail in Great Britain.

SIGNS

In quail the disease may assume an acute or chronic form. In young quail the losses may approach 100 per cent in a matter of a few days. Outbreaks may occur in birds reared on wire but are more common in birds reared on litter or ground. There may be no premonitory signs in birds dying suddenly. Such birds are usually well muscled and fat with feed still in the crops. A very striking characteristic of quail affected with ulcerative enteritis is a watery dropping containing urates (Fig. 17.1). In transmission studies the first sign of infection is a change from the normal dry and firm dropping to that of watery consistency. As the disease progresses, infected quail become listless, humped up, with the eyes partly closed and the feathers dull and ruffled. In birds affected a week or more there is a marked wasting of the pectoral muscles and eventually extreme emaciation occurs. There is a marked drop in feed consumption. The course of the disease following experimental infection is approximately three weeks with the peak of mortality occurring between 5 and 14 days following inoculation. Bass (1941b) stated that when wide distribution had occurred in quail stock, it took from 6 to 10 months for all infected birds to die out.

GROSS LESIONS

Gross lesions in quail are variable depending upon the time elapsing between infection and death. Birds dying suddenly may have a marked hemorrhagic enteritis in the upper portion of the intestine. Small punctate hemorrhages may be visible in the intestinal wall. The liver and spleen may show no gross changes in acute cases. In chronic cases the lesions become more prominent and extensive. Ulcers may occur in any portion of the intestine and ceca (Fig. 17.2). Small yellow foci with a hemorrhagic border may be seen both from the serosal and mucosal surfaces (Figs. 17.3 and 17.4). As the ulcers increase in size the hemorrhagic border tends to disappear. The ulcers may be lenticular or roughly circular in outline sometimes coalescing to form large necrotic diphtheritic areas. The lenticular shape is more common in the upper portion of the intestine. The ulcers may be deep in the mucosa or in older lesions they may be superficial and have raised edges (Fig. 17.5). Ulcers in the ceca may have a central depression filled with dark staining material that cannot be rinsed away readily. Perforation of the ulcers commonly occurs resulting in peritonitis and intestinal adhesions.

Liver lesions vary from a light yellow mottling to large irregular yellow areas of necrosis along the edges of the liver. Other

FIG. 17.3 — Chicken intestine. Note lenticular ulcers with a hemorrhagic border visible through the serosal surface.

FIG. 17.4 — Chicken intestine. Same as Fig. 17.3. Note ulcerations on mucosal surface.

FIG. 17.5 – Poult intestine with craterlike ulcerations from a natural case of ulcerative enteritis.

FIG. 17.6 – Combined ulcerative enteritis and E. brunetti in the intestine of a chicken. Note small ulcers in ceca and rectum. Diphtheritic membrane is due to coccidial infection.

liver lesions are disseminated grey foci or small yellow circumscribed foci which are sometimes surrounded by a light yellow halo effect. The spleen may be congested, enlarged, and hemorrhagic. Gross lesions are absent in the other organs. Peckham (1959) described liver, cecal, and intestinal lesions in chickens dying from ulcerative enteritis and noted that the disease in chickens is usually preceded or accompanied by coccidiosis (Fig. 17.6). Bullis and Van Roekel (1944) noticed that coccidiosis and ulcerative enteritis were often associated in poults. Witter (1952) reported complications in broiler flocks affected with coccidiosis. He found intestinal and cecal ulcerations similar to those of ulcerative enteritis in quail and, in addition, swollen

livers with pale, marginal necrotic areas. Gray et al. (1954) noted intestinal and cecal ulcerations with large areas of necrosis in the livers of chickens with hemorrhagic disease. All of these flocks had been treated with coccidiostats. Jungherr (1955) indicated that ulcerative enteritis was increasing in turkey poults and chickens (Fig. 17.7). He stated that some cases of coccidiosis did not respond to the usual coccidiostats, because of complications with ulcerative enteritis, and only when the treatment was changed to antibiotics or furazolidone did the flock improve. Chickens with ulcerative enteritis manifest signs similar to those of coccidiosis. As a result of this, flock owners usually medicate with a coccidiostat. Rosen and Bischoff (1949) re-
FIG. 17.7 — Cecal ulcerations in a turkey poult affected with ulcerative enteritis.

ported that 1 per cent sulfamethazine and 0.25 per cent sulfaquinoxaline in mash fed for 3 days had no effect on the course of ulcerative enteritis in quail. Churchill and Coburn (1915) reported on the failure of sulfonamide therapy against ulcerative enteritis. In chickens the liver lesions were either small, discrete, yellow, necrotic foci or large, irregularly shaped light yellow areas on the border of the liver (Fig. 17.8). Ulcerations were present in either the ceca, the intestine, or both. The combination of cecal and liver lesions makes the differentiation of this form of ulcerative enteritis and blackhead necessary. This can be done by histological examination or by demonstrating the ulcerative enteritis bacillus in liver smears.

Peckham (1960) described an unusual lesion of ulcerative enteritis in poults characterized by a necrotic, diphtheritic membrane occupying the middle third of the intestine. This combination of necrosis and sloughing of the intestinal mucosa appeared similar to the lesion produced by *Eimeria brunetti* infection in chickens (Fig. 17.9).

HISTOPATHOLOGY

A detailed description of the histopathology of ulcerative enteritis in quail was given by Durant and Doll (1941). Intestinal sections from acute cases revealed desquamation of mucosal epithelium, edema of the intestinal wall, vascular engorgement, and lymphocytic infiltration. The lumen of the intestine contained desquamated epithelium, blood cells, and fragments of mucosa. Early ulcers were small hemorrhagic necrotizing areas involving the villi and penetrating into the submucosa. Cells adjacent to these areas exhibited coagulation necrosis with karyolysis and karyorrhexis. Lymphocytic and granulocytic infiltration occurred in the area adjacent to the necrosis. Small clumps of bacteria were present in the necrotic tissue. Older ulcers appeared as thick masses of

FIG. 17.8 — Liver from a chicken with ulcerative enteritis. Note necrotic foci, some of which have a light yellow halo effect.
FIG. 17.9 — A necrotic diphtheritic membrane in the intestine of a poult caused by "quail disease."

granular acidophilic coagulated material mixed with cellular detritus and bacteria (Fig. 17.10). Granulocytes and lymphocytes infiltrated the area surrounding the ulcer (Fig. 17.11). In the submucosa and muscularis small blood vessels near the ulcers were occasionally occluded by bacteria.

ETIOLOGY

The isolation and identification of the etiological agent has been the subject of several investigations and, to date, confirmation of these reports is lacking. Morley and Wetmore (1936) reported the isolation

FIG. 17.10 — Transverse section of quail intestine with a large ulceration. ×80.
FIG. 17.11 — Higher magnification of area indicated by arrow in Fig. 17.10. Note cellular infiltration and dark linear masses (arrow) of bacteria. ×160.

of an organism in pure culture from the liver of diseased quail with which they produced ulcerative enteritis in quail. The organism which they described as a Gram-positive, pleomorphic, aerobic, nonmotile rod. The organism could not be isolated on solid media and on primary culture grew poorly in fluid media. The organism retained its virulence for seven subcultures but the majority of cultures soon lost their virulence.

Bass (1941a) described the isolation of a Gram-negative, anaerobic bacillus from the intestine and liver of infected quail. The medium he used for isolation was thioglycollate modified by the addition of 0.1 per cent agar. Using cultures grown in artificial media, he was able to reproduce the clinical syndrome.

FIG. 17.12 — Seven-day-old culture of quail bacillus in thioglycollate. 9th passage.

Durant and Doll (1941) tested 70 bacterial cultures they had isolated from quail by aerobic and anaerobic culture. None of these cultures reproduced the disease on feeding. On the basis of histological studies and the character of the disease, they concluded the disease was probably of bacterial origin.

Peckham (1959, 1960) reported on the isolation of a Gram-positive, spore-forming rod from the blood, liver and intestine of infected quail. The same organism was isolated from the livers of chickens and turkeys affected with ulcerative enteritis. Most of the isolations were made by yolk sac inoculation of 5–6 day chicken embryos. The intestinal suspension was heated at 70° C. for 10 minutes before embryo inoculation. Some liver suspensions were inoculated directly into embryos without treatment while other suspensions were heated at various temperatures and intervals with the maximum of 80° C. for 20 minutes. Following intraperitoneal injection of quail, 3 isolations were made by inoculating pieces of liver into thioglycollate enriched with 10 per cent horse serum. The fact that the bacillus is a spore former and resistant to heating facilitates isolation. Liver samples that might contain surface contamination can be prepared for embryo or media inoculation by triturating the tissue with a small amount of diluent and then heating at 80° C. for 20 minutes or 100° C. for 3 minutes. Yolk cultures were pathogenic when administered by the oral, intramuscular, and intraperitoneal routes.

CULTURAL CHARACTERISTICS

Growth was established in thioglycollate medium enriched with 3 to 10 per cent horse serum or defibrinated horse blood. After adaptation to thioglycollate, growth occurred as a granular mass in the lower two-thirds of the tube (Fig. 17.12). Following 8 to 10 serial passages in thioglycollate at 48- to 96-hour intervals growth was established on yolk agar, PPLO agar (Difco) with 3 per cent serum fraction, and

5 per cent horse blood agar incubated in 10 per cent CO_2, 63 per cent methane, and 27 per cent air. Initially, light growth occurred in 48 hours as discrete, smooth, raised, white, circular colonies 1 to 2 mm. in size. After adaptation, the growth was not as moist and became confluent. Growth was established on Dorset's egg slants without glycerol and on Loeffler's serum agar slants inoculated with thioglycollate cultures. Direct inoculation of solid media with infected liver did not succeed in establishing growth. The presence of viable organisms in the liver was determined by inoculation of embryos with the same suspension. The use of a staphylococcus streak on blood agar with or without reduced oxygen tension did not enhance growth. The bacillus is Gram-positive in young cultures, in liver smears from birds with necrotic foci in the liver, and in yolk smears from dead embryos. Organisms in old cultures, particularly those grown in artificial media, are decolorized more readily than those from fresh cultures. The bacillus is 3 to 4 microns long and occurs singly as a straight rod or a slightly curved rod with rounded ends. Occasionally, organisms undergoing binary fission are found joined at the ends by a fine strand.

It was noted that variations in morphology occurred with continued passage in artificial media. Coccoid forms, pleomorphic forms, and chains were sometimes seen. However, the organism still retained its rod-shaped morphology even after 14 serial passages in embryos. In embryo cultures, subterminal spores are readily formed. The spores occupy the terminal third of the cell and have a cylindrical form with rounded ends (Fig. 17.13). The spores stain readily with Wirtz spore stain. Smears of quail livers with necrotic foci revealed Gram-positive rods, free spores and rods with subterminal spores. Evidence that the livers with necrotic foci from chickens and turkeys may contain the etiological agent has been demonstrated by infecting quail per os with suspensions of triturated livers (Peckham, 1960).

TRANSMISSION

Under natural conditions the disease is transmitted by ingestion of contaminated droppings. Experimentally, the disease can readily be transmitted by feeding intestinal suspensions to quail.

Peckham (1959, 1960) reported that yolk cultures were pathogenic when adminis-

FIG. 17.13 — Blood smear from a quail with ulcerative enteritis. Note two bacteria, one of which has a subterminal spore. ×2700.
FIG. 17.14 — Large white area of degeneration in the breast muscle of a quail produced by intramuscular inoculation of a yolk culture.

tered to quail by the oral, intramuscular, or intraperitoneal routes. By these methods of inoculation, the earliest deaths occurred 18 hours after inoculation. Usually, intramuscular and intraperitoneal inoculation produced the earliest deaths. Following intramuscular inoculation of the breast muscle, a large white area of degeneration surrounded the site of inoculation, and there was a small amount of clear watery fluid between the muscle layers (Fig. 17.14). After intraperitoneal inoculation a small amount of clear watery fluid was noted in the abdominal cavity. If death occurred early, the intestinal lesions produced by intraperitoneal or intramuscular injection were either a markedly reddened intestinal mucosa or newly formed, acutely inflamed ulcers, and if death was delayed several days, the ulcers became necrotic. The livers had a mottled appearance. Yolk cultures of the bacillus were still infectious for quail after storage for 14 months at 20° C. Cultures in artificial media were nonpathogenic when fed to quail. One culture, serially passed through five transfers in thioglycollate followed by one embryo passage, was pathogenic when fed to quail.

Unsuccessful attempts were made to infect mature pheasants, turkey poults, and chicks by feeding yolk cultures which were pathogenic for quail. Yolk cultures were nonpathogenic when inoculated intraperitoneally into 3-week-old mice. The organism was not pathogenic for guinea pigs when injected into the thigh muscles using the calcium chloride technique described by Smith (1954). Shillinger and Morley (1934) observed that the degree of resistance in quail to infection varied and inconsistent results were often obtained by feeding infectious material to apparently susceptible birds. Infection in some birds appeared to build up an active immunity of considerable duration. They also noted that continued passage from one bird to another under laboratory conditions tended to decrease the virulence of the infection.

CONTROL

Control measures that have been tried include bacterins, serological tests, and prophylactic and therapeutic chemotherapy. Bass (1941b) reported that he immunized quail by two intramuscular injections of a bacterin 5 days apart. The bacterin was prepared from 24–36 hour cul-

tures grown in thioglycollate and killed with 1:10,000 dilution of merthiolate. Birds thus immunized survived the feeding of several hundred times the infectious dose for nonimmune birds.

Peckham (1962) reported the results of four trials in which attempts were made to immunize quail by single and multiple intramuscular injections of heat-attenuated and untreated yolk cultures. Although some trials gave encouraging results, other trials indicated no protection was given by the vaccination procedures.

Morris (1948) described in detail the technique of a complement fixation test for the detection of ulcerative enteritis in quail. He stated that the chronic carrier was one of the most important factors in perpetuating the disease and by the use of the complement fixation test, carriers of the disease could be detected. Comparable results were obtained in tests conducted on birds following artificial and natural infection.

Kirkpatrick et al. (1950, 1952a and b) and Kirkpatrick and Moses (1953) reported that streptomycin administered by injection, water, or feed had a prophylactic and therapeutic value against ulcerative enteritis in quail. He also found that chloromycetin at a level of 500 grams per ton of mash gave complete protection. The majority of quail that survived in groups treated with streptomycin and chloromycetin in the feed remained highly susceptible when re-exposed to infectious material. Streptomycin at a level of 60 grams per ton gave complete protection when medication was started prior to infection. He also found that the administration of streptomycin at a level of one gram per gallon of drinking water gave complete protection when administered prior to or concomitant with artificial infection. After re-exposure of one-half of the survivors in groups treated with streptomycin in the water, Kirkpatrick concluded that there were no marked differences in the development of immunity by variations in dosage of antibiotic, the time when treatment was given,

or the duration of treatment. This is in marked contrast to the results obtained in re-exposure of the survivors of a natural outbreak where it was found that these birds were completely refractory to challenge. Kirkpatrick and Moses (1953) reported on the results of using streptomycin in the water against a natural outbreak of ulcerative enteritis on a game farm. On the first day of treatment the concentration of streptomycin in the water was 5 grams per gallon and 1 gram per gallon for the next 19 days. The untreated birds sustained a 21 per cent mortality and the treated birds 4 per cent.

Peckham and Reynolds (1962) reported on the efficacy of chemotherapeutic drugs in the control of experimental ulcerative enteritis in quail. Their results confirmed those of Kirkpatrick et al. (1952b) and it was found that prophylactic administration of streptomycin at a level of 2 grams per gallon of drinking water for 25 days gave complete protection against experimental exposure. Bacitracin fed at a level of 100 grams per ton of feed also gave complete protection. In one drug trial, quail receiving streptomycin in the water or bacitracin in the feed were completely refractory to challenge after medication was discontinued. However, in another trial two groups receiving bacitracin were 100 per cent susceptible to challenge after medication was discontinued. These observations are in agreement with those of Kirkpatrick and Moses (1953) who also noted marked differences in the susceptibility of quail following medication.

In controlling outbreaks of ulcerative enteritis strict isolation should be maintained between groups of infected and healthy quail. As survivors of an outbreak may be carriers of the disease, they should not be mixed with unexposed birds. The causative organism is extremely resistant and this necessitates thorough cleaning and disinfecting of contaminated pens and equipment. Contaminated yards may remain infectious for long periods.

Outbreaks of coccidiosis in chickens and

turkeys that do not respond to the usual treatment should be carefully examined for ulcerative enteritis. If ulcerative enteritis is present, sulfonamide medication should be discontinued and bacitracin or streptomycin should be given in conjunction with the observance of good management practices.

Diseases Caused by Fungi

Advances in the past decade in the control of bacterial and viral diseases of birds have been outstanding. Although much experimental work has been done on the growth of fungi in the chicken egg embryo, very little to no progress has been made in the control of fungous diseases of birds. Fungous diseases are not the most common diseases of birds, yet they are prevalent enough to warrant economic attention.

A bibliography of avian mycosis by Chute, O'Meara, and Barden (1962) lists 709 references to fungi in birds. This bibliography brings out rare cases of reported fungous infections as well as experimental studies relating to birds and chicken egg embryos.

Aspergillosis

Aspergillosis has been observed in many birds and mammals. Frequent reference is made to the relationship of the disease in man to occupation, particularly in the so-called *gaveurs des pigeons* (pigeon feeders).

Occurrence. Aspergillosis is encountered in poultry in two main forms. Acute outbreaks in which there is a high morbidity and a high mortality may occur particularly in young birds. In adults especially, an occasional bird in a flock or aviary may become affected while the other birds remain healthy. The numerous reports in the literature suggest that nearly all species of birds may be affected. The incidence of the disease is not great, however, as evidenced by reports from diagnostic laboratories.

Etiology. It is generally agreed that *Aspergillus fumigatus* Fresenius is the most pathogenic and the most frequently encountered in disease processes due to aspergilli. The spores are widely distributed in nature, and birds frequently come in contact with them through con-

[494]
FIG. 18.1 — *Aspergillus fumigatus*. ×250. (From Nowak, *Documenta Microbiologica*, courtesy Gustav Fischer.)

taminated feed or litter. The fungus grows quite readily on the ordinary laboratory culture media at room temperature, at 37° C., and higher. Czapek's solution agar or Sabouraud's agar may be used. The colonies are green to bluish-green at first and darken with age so as to appear almost black. The colonies vary from velvety to floccose. The conidiophores are short, up to 300μ long by 2 to 8μ in diameter, the vesicles are apical flask-shaped up to 20 to 30μ in diameter, the sterigmata are 6 to 8μ by 2 to 3μ, and the conidia are globose 2.5 to 3μ in diameter, in chains forming solid columns up to 400μ by 50μ (Fig. 18.1) (Thom and Church, 1926).

Leber, according to van Heelsbergen (1929) and Lucet (1897), succeeded in isolating toxins from cultures of *Aspergillus fumigatus*. Ceni and Besta (1902) were able to extract toxic materials from spores. A toxin reported by Bodin and Gautier (1906) was similar to bacterial toxins and produced clonicotonic convulsions, paralytic symptoms, and finally death. A toxin obtained by Henrici (1939) was toxic for rabbits, guinea pigs, mice, and chickens. This toxin was hemotoxic, neurotoxic, and histotoxic. Rabbits and dogs are very susceptible to *Aspergillus* toxin. Pigeons, however, which are very susceptible to spontaneous infection are very resistant to injected toxin.

Forgacs and Carll (1955) selected strains of *Aspergillus, Penicillium,* and *Alternaria*, isolated from samples of feed associated with outbreaks of a hemorrhagic disease in poultry, and grew the cultures on grain which was fed to day-old chicks. Subsequently the chicks developed hemorrhages of the muscles, lungs, heart, gastrointestinal tract, and liver. Twenty chicks, 6 weeks of age, were given feed on which the species of *Alternaria* had been cultured alone; they died and the necropsy revealed hemorrhages throughout the carcass.

The fungous flora of young broiler chicks up to 13 weeks of age has been extensively studied by Chute *et al.* (1956). These workers observed that *A. fumigatus* may be found frequently and is not always pathogenic. The following genera were found in the lungs and air sacs: *Aspergillus, Penicillium, Paecilomyces, Cephalosporium, Trichoderma, Scopulariopsis,* and *Mucor.*

Chute and O'Meara (1958) found the air sac inoculation route with spores to be a rapid and efficient method of screening fungi for pathogenicity in chickens. The following cultures isolated from chickens were used in experimental air sac infections and revealed both spores and mycelia in the tissue: *Paecilomyces varioti, Penicillium roqueforti, Penicillium brevi-compactum, Aspergillus glaucus* groups, *Trichoderma* spp., *Trichoderma koningi, Penicillium oxalicum, Aspergillus fumigatus, Alternaria* spp., *Penicillium islandicum, Stemphylium* spp., and *Penicillium cyclopium.*

Vigorous, healthy birds apparently can withstand considerable exposure to *Aspergillus* spores occurring under natural conditions. Inhalation of a considerable number of spores, as may occur when the litter or feed are heavily contaminated, may result in infection. The occasional bird which becomes infected in a flock which is otherwise healthy may do so because of lowered resistance or severe individual exposure. Aspergillosis can readily be produced experimentally by intrathoracic injection in chickens and

pigeons. Schutz (1881), Bollinger, cited by van Heelsbergen (1929), and others observed that infection of the lungs was established following inhalation of spores. Walker (1915) reported that 5- to 7-day-old ostriches succumbed in 2 to 8 days to aspergillosis in the lungs and air sacs if spores were blown into the trachea. Intravenous inoculation resulted in pulmonary and hepatic aspergillosis. Young ostriches also developed the disease when kept on straw which had been artificially contaminated. Durant and Tucker (1935) produced the disease in a poult by feeding mash from which A. fumigatus was isolated.

In recent years several reports have been made relative to aspergillus eye infections. Reis (1940) described a keratitis in chicks caused by A. fumigatus. He described the pathology and stated usually only one eye was involved. Moore (1950) occurred in five widely separated flocks of young poults and in three breeding flocks (Fig. 18.2).

Systemic aspergillosis in poults has been reported by Witter and Chute (1952). Chute et al. (1955) also reported a systemic aspergillosis infection in 5-week-old cockerels which had been caponized. The authors considered that this resulted from a caponizing infection.

Aspergillus glaucus and A. niger may

FIG. 18.2 — Plaque from the eye of a chick with eye aspergillosis. X 2. (Chute, University of Maine)

be encountered in some cases, particularly in cutaneous lesions. Lahaye (1928) discusses cutaneous aspergillosis in pigeons. Ainsworth and Rewell (1949) reported the isolation of 45 pure cultures of *A. fumigatus*, 3 of *A. flavus*, and 1 of *A. nidulans* from 78 cases of aspergillosis in captive wild birds. Jungherr and Gifford (1944) found fungal hyphae in the cerebellum of a poult which had exhibited nervous symptoms. In another outbreak in poults showing pneumomycosis, these workers recovered *A. fumigatus*, *A. niger*, and *Paecilomyces varioti* from the internal organs. The latter was isolated also from the brain of one poult, but since fungal hyphae could not be demonstrated and the culture proved nonpathogenic, it was concluded that the symptoms and brain lesions had a toxigenic base. Bullis (1950) recovered *A. fumigatus* from the cerebrums of poults which showed incoordination and later (unpublished) *Diplococcium* sp. from the cerebrums of similar poults. *Mucor* sp. and *Penicillium* sp. and other fungi may be encountered in pulmonary mycosis, particularly in mixed infections (Baker *et al.*, 1934; Thompson and Fabian, 1932).

A case of egg-borne aspergillosis was reported by Eggert and Barnhart (1953). They suggested the fungus had penetrated through the eggshell during incubation and the recently hatched chicks were infected. Another case which was shown to be hatchery-borne was reported by Clark *et al.* (1954). From 21 ranches where 210,000 chicks were involved, there was mortality from 1 to 10 per cent. The infection could not be traced to the hatching eggs but was readily found in the incubators, hatchers, incubator rooms, and intake ducts. Symptoms and lesions were noted in some day-old chicks but generally classical lesions were observed in chicks 5 days of age.

O'Meara and Chute (1959) produced aspergillosis experimentally in hatching chicks. Chicks in the process of hatching and up to two days of age were easily infected with *A. fumigatus* spores by con-
FIG. 18.3 — Aspergillosis involving syrinx. (Bullis, University of Massachusetts)

taminating the forced draft incubator with wheat which had been seeded with *A. fumigatus* Chicks older than three days of age were resistant to infection.

Chute and O'Meara (1961) reported some unusual cases of avian mycosis. Two cases of fungous tracheitis were observed and in each case the mycelial growth extended through the cartilage.

Lesions. The lesions depend considerably on the site of infection. Either localization or generalization may be observed. Individual lesions may be observed, for example, in the syrinx (Fig. 18.3) or in a single air sac. The lungs are most frequently involved. Pulmonary lesions vary from miliary nodules up to larger nodules (Fig. 18.4). In some cases there may be localized hepatization, and in others grossly visible mycelial masses may be present in the air passages and bronchi There may be generalized involvement of the air sacs. Occasionally, a circular disc-shaped necrotic mass with a concave surface, loosely attached to which there is a circular more or less flat or convex plaque, may be observed. Various manifestations of the disease have been described. Lange (1914) recorded nodules in the lungs, the thoracic, and the abdominal cavities of chickens, ducks, geese, and pigeons. These nodules varied from pinhead or millet seed size up to the size of a pea. They were yellow in color, of an elastically soft or cartilaginous consistency, and homogeneously caseous Individual nodules

were noted on the intestinal serosa and in the parenchyma of the liver in a goose.

The nodules in the lungs of a turkey observed by Schlegel (1915) were pinhead to lentil size and were surrounded by an infiltrated or hemorrhagic corona with considerable hepatization. There were also grayish-yellow, fibrinopurulent disc- or plate-shaped masses of exudate 2 to 5 mm. thick on the pleura. Inflammation and detrital masses were present in the bronchi. The anterior thoracic, the axillary, and the cervical air sacs contained yellow caseous flat discs and masses consisting of inflammatory exudate and mycelia. The left lower, upper posterior thoracic, and left abdominal air sacs were greatly distended. The walls of these air sacs were thickened and covered with a furlike growth of mold. Adjacent to the air sacs there were lentil-sized, knob-shaped, and concentrically layered, turbid yellow, solid nodules composed of fibrin and mycelia. There were about 200 cc. of a reddish, turbid fluid in the abdominal cavity.

There were no circumscribed yellowish foci in the outbreak in chicks reported by Savage and Isa (1933). There was a diffuse grayish-yellow infiltration in the lungs with about one-third of each lung involved. The mortality was 90 per cent in this outbreak.

In pneumomycosis in a flamingo described by Mohler and Buckley (1904), the lungs were filled with nodules, and
FIG. 18.4 — Aspergillosis nodules in lungs and plaquelike formations on the serous membranes. (Bullis, University of Massachusetts)

the mucosa of the bronchi was covered with membranous masses that consisted primarily of the fungous mycelium.

Archibald (1913) found gray, round colonies of the fungus in the bronchioles in an ostrich, whereas in a case described by Jowett (1913) the lungs were covered with miliary foci.

Lahaye (1928) states that *Aspergillus glaucus* may be the cause of a disease of the skin in pigeons, particularly in young birds. Any part of the body may be affected with yellow scaly spots. The feathers in the affected areas are dry and easily broken.

Durant and Tucker (1935) observed yellowish-white nodules up to 8 × 5 mm. in the lungs of wild turkey poults being reared in captivity. The hyphae of the fungus also penetrated the tissue of the lung, and there was involvement of the adjacent air sacs.

In canaries observed by de Jong (1912) there were small whitish-yellow, crusty coatings on the tongue, palate, aditus laryngis, and in the trachea and syrinx. Caseous foci in the lungs and caseous coatings on the pleura and peritoneum were also observed.

The histological picture as described by Nieberle (1923) consists of focal pneumonia, multiple necrosis, and nodular formations which resemble tubercles. The diffuse pneumonic foci are indicative of the fibrinous or catarrhal pneumonia. The alveoli, bronchioles, and bronchi are filled with mucus, stained fibrin, nuclear fragments, detritus, leucocytic and inflammatory cells, and mycelia. The mycelia penetrate the walls, and the surrounding pulmonary parenchyma shows an exudative cellular inflammation or necrosis. The tuberclelike nodules show in the center a radiating turf of hyphae surrounded by a reactive inflammatory wall which resembles granulation tissue. Foreign body giant cells are frequently observed. The fruiting organs (conidiophores, sterigmata, conidia) occur more frequently in the air sacs.

Symptoms. Dyspnea, gasping, and ac-

celerated breathing may be present. When these symptoms are associated with other respiratory diseases such as infectious bronchitis and infectious laryngotracheitis, they are usually accompanied by gurgling and rattling noises, whereas in aspergillosis there usually is no sound. Guberlet (1923) ascribed somnolence, inappetence, emaciation, increased thirst, and pyrexia to aspergillosis. Cases under his observation emaciated rapidly and showed a diarrhea in the later stages. Dysphagia was noted in cases in which the esophageal mucosa was involved. Mortality was as high as 50 per cent in confined birds on some farms, whereas birds running out of doors were more resistant and escaped infection entirely on other farms. According to van Heelsbergen (1929) some investigators have reported serous excretions from the nasal and ocular mucosa. Extreme dyspnea was recorded by de Jong (1912) in canaries. In an outbreak in wild turkey poults reared in captivity, described by Durant and Tucker (1935), mortality began at 5 days, reached a peak at 15 days, and subsided at three weeks of age. Some affected poults died in convulsions within 24 hours. In two lots of poults 200 survived out of 785. Gauger (1941) reported an outbreak in adult chickens in which about 10 per cent of the flock was affected with symptoms not unlike those shown by birds affected with laryngotracheitis and in which there was no abnormal mortality, but the egg production was temporarily lowered. Reis (1940), cited by Hudson, and Hudson (1947) have reported infection of the eyes in chicks two to five weeks of age. Infection in Reis's cases originated in sawdust litter and in Hudson's cases in bagasse litter. The outbreaks were characterized by the formation of a yellow cheesy pellet beneath the nictitating membrane which caused the lids to bulge (Fig 18.2). There was some central ulceration of the cornea in the older chicks.

Diagnosis. The fungus can be demonstrated by cultural methods if it cannot be demonstrated in fresh microscopic

FIG. 18.5 – Granuloma of lung from chick infected with A. fumigatus. (Chute, Univ. of Maine)
FIG. 18.6 – Viscera and musculature with plaques from a chicken experimentally infected in the air sac with A. fumigatus. (Chute, Univ. of Maine)

preparations. Occasionally, masses of the fungus are visible to the naked eye in the air passages of the lungs (Fig. 18.5), in the air sacs (Fig. 18.6), or in the abdominal cavity. The typical fruiting heads may be readily demonstrated in such lesions. Demonstration of the fungus by direct examination may be impossible in the small caseous nodules seen particularly in the lungs.

Prophylaxis and treatment. The avoidance of moldy litter or feed serves to prevent outbreaks of aspergillosis. An examination of the premises or materials used

for feed or litter will usually reveal the source of the infection.

Treatment of affected individuals is usually considered useless. They should be sacrificed and the offending infective material removed. Lahaye (1928) reported favorable results in the treatment of aspergillosis of the skin in pigeons by the use of $HgCl_2$ solution 1:500. The surface of the body was moistened or the birds dipped into the solution, following which they were rinsed in lukewarm water and dried.

Favus

Favus is a chronic dermatomycosis affecting chickens, occasionally turkeys and some other birds, animals, and man. In the fowl, the comb is almost always attacked, but other portions of the head may be affected, and in severe cases the disease spreads to the feathered portions of the body.

Occurrence. Favus occurs only infrequently in the United States. Possibly this is due to the lesser number of the heavier Asiatic breeds which are reported to be more susceptible The disease is reported to be quite common in France.

Etiology. The causative fungus in the fowl is *Trichophyton megnini (Achorion gallinae)*. Cultivation on Sabouraud's glucose agar is satisfactory. It is sometimes of assistance to cover the inoculum with absolute alcohol and evaporate the alcohol to destroy the contaminating bacteria. Cultures grow slowly. Colonies develop as small round discs which are white and velvety and have small central cups and radial grooves. A reddish pigment varying from rose or strawberry red to a deep raspberry diffuses through the medium. Microscopically, the branched mycelium is twisted, the septa are irregularly spaced, the spores are in clusters, and there are nodular organs and fuseaux. Typical lesions may be produced by inoculation of the scarified comb. Mice, rabbits, or

guinea pigs may also be inoculated, although the lesions are not so typical in the guinea pigs (Dodge, 1935; Jacobson, 1932). Torres and Georg (1956) reported a case of *Trichophyton gallinae* in the scalp of a 4-year-old Puerto Rican girl. Experimental infections were produced in several chickens and guinea pigs.

Symptoms and lesions. Lesions usually develop first on the comb. As the fungus spreads, white spots develop, the surface of which scales off, and the comb may appear as though sprinkled with flour (Fig. 18.7). Young birds with well developed combs are most likely to be affected. The wattles and unfeathered por-

FIG. 18.7—Favus of comb and wattles. (Bullis, University of Massachusetts)

tions of the head may be affected. As the disease progresses, the scaly deposits become thicker and form a wrinkled crust. Spontaneous recovery is reported in some cases. In other cases the fungus spreads to feathered portions of the body. The feathers fall out in patches. The skin becomes thickened in the affected areas and covered with scales and crusts, especially around the feather follicles. A moldy odor may be detected. Matruchot and Dassonville (1899) reported the appearance of favus simultaneously on the feathered and nonfeathered portions of the body. Symptoms were not extensive in the cases observed by Sabouraud et al. (1909). Schlegel (1909) reported depression, weakness, emaciation, anemia, cachexia, and icterus in affected chickens. In some birds, in addition to the external lesions, there were necrotic foci, nodules, and yellowish caseous deposits on the mucosa of the upper respiratory and digestive tracts. Occasionally, the bronchi and lungs were affected and necrotic caseous inflammation was observed in the crop and small intestine. The favus fungus could be demonstrated microscopically in these lesions. The fungus spreads slowly from bird to bird by direct contact and by the scales which become detached from affected individuals and contaminate the premises.

Diagnosis. The characteristics of the gross lesions may be sufficient for diagnosis. If this is inconclusive, the fungus can be checked microscopically and culturally. Transmission of the disease to laboratory birds or animals or a study of the contagious nature of the disease in the flock may be helpful.

Prophylaxis and treatment. Care should be exercised in the addition of new birds to the flock. Infected houses should be cleaned and disinfected. Badly affected birds should be sacrificed. Mildly affected birds should be segregated, and treatment can be tried if desired. The majority of mildly affected birds will recover without treatment. Several individuals have been observed in which various treatments were used on one side of the head and the opposite side was left untreated, and recovery was similar on each side. Van Heelsbergen (1929) suggests the following remedies: iodine and glycerine (tinct. iodine 1.0, glycerine 6.0), green soap, and 5 per cent phenol solution, or bichloride of mercury (1:500), the latter to be used particularly on the body. Beach and Halpin (1918) found an ointment of formaldehyde and vaseline to be effective. This is prepared by melting vaseline in a jar in a water bath. Five per cent by weight of commercial formalin is added, the cover tightened, and the mixture shaken until the vaseline has solidified. One or two applications well rubbed into the lesions usually suffice. Riedel (1950) observed recovery in a group of artificially infected chickens within 20 days following a single application of a 2 per cent mixture of quaternary ammonium compounds consisting of equal parts of alkyl-dimethyl-benzyl-ammonium chloride and a l k y l-dimethyl-dichlor-benzol-ammonium chloride.

Thrush (Mycosis of the Digestive Tract)

Stomatitis oidica, muguet, soor, moniliasis, oidiomycosis, and sour crop are other terms applied to mycotic affections of the digestive tract.

Occurrence. Mycosis of the digestive tract probably occurs rather frequently, but in many cases it does not appear to be of sufficient significance to be considered seriously. Numerous general discussions of poultry diseases fail to mention this disorder, and the paucity of diagnoses in reports from diagnostic laboratories suggests that it may not be of great consequence. However, serious outbreaks have been reported in many species of birds Animals and man are also affected Thrush has been observed in chickens, pigeons, geese, turkeys, pheasants, ruffed grouse, and quail.

Etiology. The etiological significance of yeastlike fungi in affections of the digestive tract of man was recognized by Langenbeck in 1839. Questions relating to the validity of species described and their generic nomenclature have retarded a proper understanding of this type of disease. Jungherr (1935b, 1934) found *Monilia albicans*, *Monilia krusei*, and *Oidium pullorum* n s. to be associated with cases of thrush, but considered that *M. krusei* was not of etiological significance. *Mucor* sp and aspergilli were also found in association with some cases. Hinshaw (1933) reported that *M. albicans* was found in most cases of thrush in turkeys and chickens which came to his attention. Both investigators considered that the mycotic infections are apt to be associated with unhygienic surroundings and perhaps secondary to other debilitating conditions Eberth (1858) and Schlegel (1912) identified organisms observed by them as *Oidium albicans*.

The studies of Worley and Stovall (1937), Benham (1931), Martin and associates (1937), and others indicate the complexity of the problem. Stovall (1939) pointed out a means of improving the present uncertain status. He suggested a

specific set of environmental conditions under which the biological characteristics of the organism were constant and could be demonstrated. Jungherr's (1934) characterization is as follows: "*Monilia albicans*: It is of widespread occurrence in gallinaceous birds, pathogenic to birds and also to rabbits on intravenous injection, and is indistinguishable from strains isolated from human sources. On Sabouraud's agar it produces a whitish, creamy, high-convex colony after incubation for 24 to 48 hours at 37°C. Young cultures consist of oval budding yeast cells, about 5½ by 3½μ in dimension. Older cultures show septate hyphae and occasionally spherical, swollen cells with thickened membrane, the so-called chlamydospores. In Dunham's peptone water containing 1 per cent fermentable substance and 1 per cent Andrade's indicator, the organism produces acid and gas in dextrose, levulose, maltose, and mannose; slight acid in galactose and sucrose; and does not attack dextrin (variable according to brand), inulin, lactose, and raffinose. Gelatin stab cultures show short, villous to arborescent outgrowths without liquefaction of the medium."

The term "medical monilias" is frequently used in connection with the generic term Monilia since the term Monilia is also used for a separate group of fungi. Most workers have accepted the decision of an informal group meeting at the Third International Microbiological Congress in 1939 and use Candida as a generic name to replace the familiar but invalid *Monilia* (Skinner, 1947). *Candida albicans* is the most frequently isolated etiological agent associated with the disturbance commonly referred to as moniliasis

Symptoms and lesions. The symptoms are not particularly characteristic. Affected chicks show unsatisfactory growth, a stunted appearance, listlessness, and roughness of the feathers. Lesions occur most frequently in the crop (Fig. 18.8) and consist of a thickening of the mucosa with whitish, circular, raised ulcer for-

mations, the surfaces of which tend to scale off. Pseudomembranous patches and easily removed necrotic material over the mucosa are not uncommon. The mouth and esophagus may show ulcerlike patches. When the proventriculus is involved, it is swollen, the serosa has a glossy appearance, and the mucosa is hemorrhagic and may be covered with a catarrhal or necrotic exudate. Histologically, Jungherr (1933a) reports the crops "showed extensive destruction of the stratified epithelium deep in the Malpighian layer and quite often walled-off ulcers or extensive diptheroid to diphtheritic membranes. The lesions were characterized by the absence of inflammatory reaction." Periportal focal necrosis in the liver in some cases suggested a toxic action upon the system.

The frequent association of mycosis of the digestive tract with other debilitating conditions such as gizzard erosions and intestinal coccidiosis must be considered. Gizzard erosions as such probably are not directly related to thrush. Likewise, the thickened intestine with watery contents frequently noted in cases of thrush is probably due to coccidiosis or other protozoan infections.

In the case of thrush reported by Eberth (1858), the esophagus, crop (Figs. 18.8 and 18.9), and proventriculus showed an ulcerated and scaly condition. The spores and hyphae of what he termed Oidium albicans could be readily demonstrated in the lesions. The proventriculus was the principal organ involved in the cases observed by Schlegel (1912). The mouth, pharynx, and crop were, however, involved in some cases. Schlegel (1921) also observed the disease in geese. Diphtheroid lesions were noted in the proventriculus and small intestine. Abscess formations were present under pulpy, soft, grayish-white to brown-

FIG. 18.9 — Mycelia in stratified squamous epithelium of crop. Gridley stain. (Chute, Univ. of Maine)

ish-red necrotic masses. Hinshaw (1933) reported thrush in twelve flocks of turkeys, and the lesions were similar to those noted in chickens. Blaxland and Fincham (1950) studied five serious outbreaks in young turkeys. Their observations supported previous conclusions that moniliasis is likely to be associated with unhygienic surroundings and other debilitating conditions, but spread of infection appeared definite in many instances. Zürn (1882) and Klee (1899) described the disease in pigeons. Lahaye (1928) pointed out the similarity between thrush and pox in the pigeon. He demonstrated pox virus in many cases suspected of being thrush.

Diagnosis. Observation of the characteristic proliferative, relatively noninflammatory lesions, together with resultant heavy growth on primary cultures, serves to diagnose thrush. Because of the possibility of cultivation of *C. albicans* from apparently normal tissues, an original heavy growth is considered essential for diagnosis. The recognition of spores and more especially hyphae in fresh smear preparations is attended with some difficulty. Miliary abscesses are produced in the kidneys of rabbits injected intravenously (Benham, 1931).

Underwood (1955) described an instrument known as a McCarthy's foroblique panendoscope which was used to diagnose experimental crop moniliasis. This instrument was equipped with a viewing lens and an independent light source. Birds were starved for 12 hours in order to empty the crop to allow a clear view of the mucosa. A normal crop appeared to be light pink with a glistening smooth surface having numerous shallow convolutions, whereas a fungus-infected crop showed severe corrugations or mild whitish streaks, erosions, or diphtheritic formations and a deep red surrounding mucosa.

Course. Young birds are more susceptible to mycosis of the digestive tract than are older birds. Thus as an infected group of birds grow older they tend to overcome the infection. Jungherr (1933a) observed an outbreak in which the losses amounted to 10,000 chicks out of 50,000 that were less than 60 days of age. He also reported (1934) that turkeys under four weeks of age succumbed rapidly to infection, but that outbreaks in turkeys three months of age resulted in a high percentage of recoveries.

Prophylaxis and treatment. Since mycosis of the digestive tract is apt to be related to unhygienic, unsanitary, overcrowded conditions, these factors should not be allowed to exist, or should be corrected. Jungherr (1933b) found that denatured alcohol and coal-tar derivatives were ineffective as disinfectants and suggested that iodine preparations be used. As a treatment he recommends that following an Epsom salt flush, one level teaspoonful of powdered blue stone (copper sulfate) be added to each 2 gallons of drinking water in nonmetal containers every other day during one week. Hinshaw recommends that a 1:2,000 solution of copper sulfate for turkeys be used as the sole source of drinking water during the course of the outbreak. Affected birds should be segregated. Lesions in the mouth can be treated by local application of a suitable antiseptic. The appearance of the disease in very young chicks sug-

gests the surface of the egg as a source of infection. Such a possibility could be removed by dipping the eggs in an iodine preparation prior to incubation.

Underwood et al. (1956), in experimental moniliasis produced in chicks and poults, found copper sulfate was ineffective for treating or preventing the disease.

Nystatin has been studied by Gentry et al. (1960) and by Kahn and Weisblatt (1963). One group reported that 220 mg.

Nystatin per kg. of diet fed was effective in eliminating moniliasis in a flock of turkeys. The other group found in experimental infections with C. albicans in both chickens and turkeys that crop score values appeared to be significantly reduced in the group fed the lowest level of Nystatin (11 mg/kg). The highest level of Nystatin (110 mg/kg) fed showed a very significant protection against mycotic infection.

Sarcosporidiosis

Sarcosporidiosis appears to be neither widespread nor economically important in birds, at least in the United States. The striated muscles of mammals are involved principally, although reptiles and birds are sometimes affected. Among mammals, sarcosporidiosis is most likely to be found in sheep, swine, cattle, and horses. A few cases in man have been reported.

Occurrence. Erickson (1910) listed 8 orders, 13 families, 19 genera, and 20 species of birds as being affected. Some of the better known hosts are the chicken, domestic mallard, wild mallard, black duck, gadwall, American pintail, blue winged teal, shoveller, turkey vulture, and English sparrow. Ducks are especially likely to be affected, and Erickson states that all recorded cases are in puddle or dabbling varieties. Hall (1925), in listing

a case in a domesticated duck from a market in Washington, D.C., suggested that the infection might be of economic importance because the flesh would have been judged unfit for consumption, but there seem to be no other similar reports. Beaudette (1941) suggests that sarcosporidiosis is probably widespread but escapes notice because of the absence of symptoms in affected birds, and infection is not discovered unless the muscles are exposed. Reports of infection in chickens are uncommon and include Germany, Kuhn (1865); the United States, Stiles (1894) and Hawkins (1913); Hungary, von Ratz (1908); Bulgaria, Krause and Goranoll (1933); and Brazil, Reis and Nobrega (1936).

Symptoms, lesions, diagnosis. The lesions may be so small as to escape detection except by microscopic examination. When larger and present in considerable numbers, the musculature has a finely streaked or "wormy" appearance (Fig. 18.10). The individual sarcocysts, frequently called Miescher's tubes or sacs, are usually elongated masses, the long axes of which are parallel to the muscle fiber. Large cysts are sometimes referred to as Balbiania. The sarcocysts in the case reported by Stiles (1893) were 1.0 to 6.0 mm. in length by 0.18 mm. in breadth; in the case reported by Mathews (1930), they were 1 × 3 mm. These are larger than most cases reported in birds, but some reports in mammals range up to 5 cm. in length. An individual cyst when removed has a whitish or creamy appearance and is cylindrical with somewhat pointed ends and appears slightly lobulated on the surface. The cyst is divided by septa into compartments. The compartments in a mature cyst are filled with spores (Rainey's corpuscles) which are variously described as banana, crescent, sickle, or comma shaped. The spores are 3 to 15μ in length and 1 to 4μ in width. The compartments in the center of an old cyst tend to undergo degeneration. Mathews (1930) called attention to a variation in connective tissue and inflammatory response which was proportionately greater around cysts with more degeneration (Fig. 18.11). The sarcocysts start development within muscle fibers, but as they enlarge the fibers are destroyed and the larger cysts are intermuscular. Apparently the sarcocysts do not seriously injure their hosts. Most reports are on birds which were considered normal when killed. Very heavy infestations may possibly cause symptoms. Mice may be killed by heavy doses, and this suggests that the same may be true in larger animals and birds.

Etiology. Following the discovery by Miescher (1843) of Sarcosporidia in the muscle tissue of a mouse, they were first named Synchytrium miescherianum by Kühn (1865). This genus was, however, already in use to describe a group of funguslike organisms, and the genus

FIG. 18.10 — Severe sarcosporidiosis in a duck.
(Becker, Iowa State University.)

FIG. 18.11 — Sarcosporidia in breast muscle of chicken. ×150. (Biester, Iowa State University.)

Sarcocystis was established by Lankester in 1882. There are names of many species in the literature designated principally with respect to the animals infected, but the organisms have not always been host-specific, and the morphological differences are not substantial except in relation to size of the cysts. Alexeieff (1913) concluded that there was no reliable ground for distinguishing the supposed species of Sarcocystis and that all belong to one species, S. miescheriana. Hagan (1943) suggests that S. miescheriana has priority if all are considered as a single species, otherwise this term would apply only to infection in the pig. Sarcocystis rileyi, Stiles (1893), has been the term applied to the presumed infective protozoan in ducks since Riley told Stiles (1893) that the lesions noted by Walsh and Riley (1869) and believed by them to be similar to Cysticercus cellulosae of pork were identical with Stiles's Sarcocystis. Hawkins (1943) compared sarcosporidiosis in the chicken, the mallard, the domestic mallard, and the black duck and stated that all were apparently the same species.

The life history of Sarcosporidia is incompletely known and only brief mention is made here. Although Theobald Smith (1901, 1905) and others have reported transmission, particularly in mice, by feeding flesh containing mature sarcocysts, it is probable that this would not have been accomplished had the eating of feces been prevented. Spindler et al. (1946) established infection in swine by feeding feces and/or urine from animals and birds which had been fed muscles containing sarcocysts. Flesh from infected swine was fed to pigs, dogs, cats, rats, mice, and chickens. The feces and/or urine from these animals and birds were not infective for 15 days after consumption of the infected flesh but contained a stage of Sarcocystis thereafter which was infective for swine. These findings are in harmony with those of Negre from 1910 to 1918 (cited by Spindler et al., 1946). Scott's (1930, 1943) reports which include extensive surveys of the literature and Babudieri (1932) should be consulted by anyone involved in research on sarcosporidiosis. There is a latent period of at

FIG. 18.12 — Miescher's sacs, showing arrangement of "septa" (A, B, and C); their jointed structure (C, D, and F); and attachment of the Rainey's corpuscles (spores) to the "septa" (E and F). Sections were stained with Gram's stain. A, B, and C are from a naturally infected sheep. D, E, and F from a naturally infected wild duck; D, E, and F from a naturally infected wild duck. (Spindler, Proc. Helminth. Soc. Wash. 14:28, 1947.)

least six weeks between the time of exposure and the development of sarcocysts in the muscles. What happens during this time or the mode of escape of infective material from infected muscle is uncertain, but presumably those processes take place through the blood stream.

There has been considerable discussion as to whether the etiological agent is a protozoan or a fungus, and Wenyon (1926) suggested that the Sarcosporidia probably are fungi. Spindler and Zimmerman (1945) reported an investigation which showed that the infective agent in swine is a fungus and not a protozoan. An *Aspergillus* sp. was recovered by aseptically rupturing sarcocysts or Miescher's sacs into dextrose culture solution. Young pigs injected with or fed conidia harvested from the cultures harbored typical sarcocysts in the muscles at necropsy four to six months after exposure. A fungus like that injected

was recovered on cultures from the mature sarcocysts. Spindler (1947) prepared histological sections from a sheep and a duck in a study of the internal structure of Miescher's sacs. The sacs contain a network of jointed hyphaline structures (Fig. 18.12A, B, C, and D). The septa divide the sac into compartments (Fig. 18.12B and C). These structures appear jointed (Fig. 18.12C, D, and F). Rainey's corpuscles (spores) are shown attached to the septa (Fig. 18.12E and F). The staining reaction of the structures was found to be characteristic of fungi. This was confirmed by finding a delicate septate mycelium by heating Miescher's sacs from sheep, cattle, and birds in 30 per cent KOH solution and staining the residue with lacto-phenol cotton blue solution.

These findings in sarcosporidiosis will tend to redirect investigations and may hasten the procurement of definite information on many points which are not understood at present. Investigations are likely to be more intensive in mammals, particularly swine and sheep, than in birds because of the relative economic importance.

The Avian Leukosis Complex

Leukosis signifies a group of diseases which is characterized by autonomous proliferation of the precursors of blood cells. The term has largely replaced the older name leukemia (white bloodedness) principally because changes in the circulating blood, as implied by the name, are not an invariable pathologic feature.

Avian leukosis was first studied in a systematic way by Ellermann and fowl paralysis by Marek, at the beginning of the present century. Since both of these conditions often occur in the same flock, share a tendency toward tumor formation, and are of major economic importance, they are discussed under one chapter, without implying etiologic unity.

Although there is no universal agreement on the diseases which should be included in this chapter, the term avian leukosis is retained for its usefulness in focusing attention on the im-

portance of the problem to the poultry industry. The most interesting advances, namely the production of resistance-inducing-factor-free flocks and the ready transmissibility of the fowl paralysis syndrome, are of such recent date that their impact on final classifications can not be appraised at this time. Eventually this chapter must deal with the entire problem of avian viral tumors.

Most of the studies have dealt with the common fowl. The knowledge on corresponding diseases is incomplete in other species of birds, some of which have proved susceptible to experimental transmission of chicken leukosis. Reciprocal transmission of fowl paralysis from chicken to pheasant (and perhaps turkey) seems possible.

The development of our knowledge on the avian leukosis complex is outlined in the historical part; the various pathologic manifestations are discussed as independent entities as they present themselves

* Deceased April 16, 1965.

[512]

in practice, while cause and control are taken up from a common point of view.

HISTORY

The varied opinions on, and the practical importance of, the avian leukosis complex are reflected in the large number of references to this disease group in the literature. Comprehensive reviews have been prepared by Biely and Palmer (1932), Jármai (1934), Olson (1940), Engelbreth-Holm (1942), Furth (1946), Oberling and Cuérin (1954), Chubb and Gordon (1957), Biggs (1963), and Beard (1963a). The literature is selected from the standpoint of tracing the contributions which form the framework of our present concept of the avian leukosis complex.

Fowl paralysis. Under the term polyneuritis, Marek (1907) described a disease of chickens which was characterized by lameness and variable enlargement, due to mononuclear infiltration, of the peripheral nerves. In studying a similar disease in the North Atlantic States, Kaupp (1921) observed its frequent association with blindness. The first positive transmission experiments were reported by Van der Walle and Winkler-Junius in Holland (1924). The disease was studied from a pathologic point of view by Doyle (1926, 1928) and by Pappenheimer and his associates (1926, 1929a, b), who introduced the term neurolymphomatosis gallinarum. The last-mentioned authors pointed out the frequent association of visceral lymphomata originating from the ovary with infiltrative lesions in peripheral nerves, brain, and iris, and produced evidence of the transmissibility of the disease in about 25 per cent of the experimental birds. They believed neurolymphomatosis to bear no relationship to Ellermann's form of leukosis. The transmissibility of neurolymphomatosis has been questioned frequently in the literature (Olson, 1937).

Recently, however, Sevoian and his associates (1962, 1963, 1964) reported ready reproduction of the disease by inoculating day-old chicks of the Cornell S-line with field lymphomatosis tumors either as cellular or cell-free material, via the peritoneal or aerosol route. Vindel (1962) and Biggs and Payne (1963) likewise reported positive results in transmission experiments with Marck's disease. In a subsequent communication Vindel (1964) expressed the opinion that internal parasitism, especially coccidiosis, is epizootiologically related to Marek's disease, and that the evolution of the lesions in this disease may be brought about by a process of autoimmunization.

In a differential study of neurolymphomatosis and the lymphatic form of leukosis, Furth (1935) pointed out that the former is of frequent occurrence, associated with clinical paresis, and characterized by small-cell lymphocytic infiltration of the peripheral nerves and viscera, without blood or bone marrow involvement; the condition was found by him to be transmissible only by viable cells. Campbell (1954, 1956, 1961) and Darcel (1957) considered the condition to be purely inflammatory in character. Biggs (1961) agreed with this concept but was unable to differentiate histologically between "inflammatory" and "neoplastic" lymphoid reactions.

Fowl leukosis. Leukosis in the common fowl was first recorded by Caparini in 1896, according to Olson (1940). Extensive experimental studies of the condition were undertaken by Ellermann and his associates (1908, 1922, 1923), who recognized three general forms of avian leukosis, namely leukemic or aleukemic myeloid leukosis, intravascular "lymphoid," i.e., erythroid leukosis, and extravascular lymphatic leukosis, all of which were considered to be transmissible and caused by the same filterable virus.

This subject presented an intriguing problem to modern leukemia research in man and animals and was reopened in this country by Furth (1931a), who discovered a new strain of readily transmissible leukosis which conformed to Ellermann's intravascular "lymphoid" form; a rare subvariety with little blood involvement was described as anemic erythroleukosis (1931b).

Erythroblastosis. The characterization of

erythroleukosis was soon confirmed and extended, especially in Denmark, by Engelbreth-Holm and Rothe Meyer (1932) who suggested the term erythroblastosis and by Oberling and Guérin (1934) in France. Although "pure" strains of erythroid and myeloid leukosis were observed by Jármai (1930) and Nyfeldt (1934), the two forms tended to occur in a "mixed" form (Furth, 1931a) and were believed to be caused by the same filterable virus. In more recent times the extensive studies by J. W. Beard and his group on erythromyeloblastic leukosis (Eckert et al., 1951) resulted in the recognition of erythroblastosis as a morphologic and etiologic entity (Eckert et al., 1956).

Myeloblastosis (granuloblastosis). Leukemic myeloid leukosis of Ellermann was observed by Furth (1931a) and others in serial transmission experiments with strains of erythroblastosis. Olson (1936) discussed this disease under the heading of granuloblastic leukosis. The condition designated by Eckert et al. (1953) as erythromyeloblastic leukosis was identified morphologically as myeloblastosis by Burmester (in Eckert et al., 1953) and subsequently established as an etiologic entity by Beard (1956). While Brion and Fontaine (1963) pointed up the differences in physical, chemical, and antigenic properties between the viruses of myeloblastosis (strain A) and erythroblastosis (strain R), by electron microscopic examination these virus particles appeared to be of the same morphology (Bonar et al., 1963).

Lymphomatosis. Lymphatic leukosis represented the only extravascular form in Ellermann's classification of transmissible avian leukosis. Later his erstwhile collaborators, Andersen and Bang (1928), expressed doubt as to its transmissibility. That this disease constituted an independent nontransmissible entity was maintained by Mathews and Walkey (1929), who suggested the designation lymphadenoma and separated it sharply from neurolymphomatosis. This view was upheld by Feldman (1932), and by Feldman and Olson (1933), who used the term lymphocytoma for the aleukemic neoplastic

disease for which transmissibility had not been demonstrated and for which the type cell was the undifferentiated lymphocyte. Oberling and Guérin (1934) recognized differences between the nontransmissible extravascular forms and the transmissible intravascular ones. Furth (1935) agreed with the definition of lymphocytoma insofar as the "spontaneous" extraordinary enlargements of the liver were concerned, which condition he termed hepatolymphomatosis.

While it would appear from the foregoing statements that three separate entities have to be recognized, namely, neurolymphomatosis, transmissible erythromyeloblastosis, and nontransmissible lymphocytoma, other studies tended to break down the boundaries. Johnson (1932) was unable to differentiate lymphocytoma from the visceral lymphomata which had been described by Pappenheimer et al. (1926) in cases of neurolymphomatosis, and believed this association to be so common that he proposed the generic term lymphomatosis for the specific "neural" and "visceral" subdivisions. Furth (1933) developed a transmissible agent (strain 2) which was capable of causing what he also termed lymphomatosis and at times myelocytomatosis and endothelioma. To distinguish from neurolymphomatosis, he (1935) defined lymphomatosis as a rare disease which was not associated with clinical paresis; pathologically it was characterized by anemia, large-cell lymphocytic leukemia, and tumorous infiltrations of the same cell type in the visceral organs and occasionally the peripheral nerves; the disease proved easily transmissible by cell-free material. The term lymphomatosis was thus used in an etiologically and pathologically equivocal sense by Johnson and Furth. Experimental studies on the transmissibility of visceral lymphomatosis by Davis and Doyle (1947, 1949) and Davis et al., (1950) indicated that the incidence of the visceral type alone could be increased by inoculation. Supported by the analysis of extensive field material, this group of authors (Davis et al., 1947) considered

visceral lymphomatosis as a separate entity, distinct from neural lymphomatosis, a view held by the workers of the United States Bureau of Animal Industry Regional Poultry Research Laboratory (1951).

As stated, endotheliomata were observed by Furth (1933) in passages of strain 2. Starting with material from a case of neurolymphomatosis, Jungherr (1937) likewise observed endotheliomata. It would appear that this condition is sometimes an expression of lymphomatosis.

An uncommon hypertrophic osteopathy of chickens has been described in general ornithopathology under various terms such as hyperplastic osteitis (Reinhardt, 1930) and diffuse osteoperiostitis (Pugh, 1927). Transmission studies on this condition by Jungherr (1935) and Jungherr and Landauer (1938) tended to show that certain strains of lymphomatosis carry hypertrophic-osteopathic potentialities, for which the term osteopetrosis gallinarum was suggested.

Newer transmission experiments in a relatively pure form by Holmes (1958, 1959) and Fritzsche (1963) and pathologic and biochemical follow-up studies by Bell and Campbell (1961) suggested a specific virus as the etiologic factor (Holmes, 1961). On the other hand, the multiple cell response to a well-studied tumor virus, BAI strain A of myeloblastosis, included osteopetrosis (Heine et al., 1963), and field strains of visceral lymphomatosis likewise produced this condition in a good percentage of the inoculated inbred chicks (Burmester and Fredrickson, 1961).

Olson (1911) described a transplantable lymphoid tumor of the chicken with an unusually short incubation period that, according to gross and histopathologic features, would fall under the classification of lymphomatosis. Designating such a tumor as transplantable lymphosarcoma, Pentimalli (1911) made similar observations.

Intensive studies of the Olson tumor and similar highly malignant tumor strains by Burmester and his associates hold promise of clarifying the etiologic relationship of the various forms within the avian leukosis complex. In their hands (Burmester et al., 1944) the Olson tumor maintained its virulence almost unabated when frozen slowly and stored at $-65°$ to $-76°$ C for 391 days.

By intraperitoneal injections of young chickens with tumor tissues which morphologically were indistinguishable from lymphocytoma, visceral lymphomatosis, or "lymphoid tumors," Burmester and Prickett (1945) were able to develop several additional highly malignant tumor strains. Chickens immunized against a transplantable tumor were no more resistant to spontaneous neural or visceral lymphomatosis than comparable controls in the experience of Burmester (1947b) and Olson (1947). The latter author also found chickens spontaneously affected with neural lymphomatosis to be fully susceptible to implants of a lymphoid tumor.

Darcel (1953) compared the behavior of the Olson tumor (RPL-12) with two other strains isolated by Burmester and found them essentially similar. Intramuscular transplantation caused the appearance of intravascular neoplastic cells in the liver, but the mechanism of internal spread could not be established.

Transplantable tumor tissues and the plasma of lymphoid tumor-bearing chickens were shown to contain a filterable agent, capable of inducing visceral lymphomatosis and osteopetrosis after an incubation period from two to six months (Burmester et al., 1946a; Burmester, 1947a). The existence of filterable agents producing lymphoid tumors and osteopetrosis was confirmed by serial passage in chickens (Burmester and Cottral, 1947). Although finding variations in the transmissibility of the disease from different donors (Burmester and Dennington, 1917), avian lymphomatosis could be propagated with cellular as well as cell-free preparations (Burmester, 1947b). In this series the incidence of osteopetrosis and neural lymphomatosis was surprisingly low, which suggested different etiologic agents for the latter conditions. Burmester (1947c) ex-

pressed the opinion that many cases of natural lymphomatosis carry masked *lymphoid tumor agents*.

In quantitative follow-up studies, Burmester and Gentry (1956) made the interesting observation that the virus of visceral lymphomatosis, as represented by plasma filtrates of RPL-12, tended to cause early intravascular erythroblastosis, when given in high doses, and late extravascular lymphomatosis when given in low doses. These changes were accompanied by a low, but significant, incidence of osteopetrosis in all inoculated birds, especially the males. This dual cytotropism maintained itself in pathogenicity tests.

In detailed studies of the pathogenicity of RPL-12, Gross et al. (1959) showed that the virus may induce not only visceral lymphomatosis but also erythroblastosis, hemangiomatosis, and osteopetrosis. From the same data Burmester et al. (1959a, 1960a) brought out the importance of the host-virus interrelationship on the pathologic response, especially with respect to age and genetic background of the host, and source, dose, and route of inoculation of the virus. For the principal neoplastic manifestation, i.e., erythroblastosis and visceral lymphomatosis, age of host and virus concentration in inoculum proved statistically to be the important variables affecting the responses (Gross et al., 1962). Partial fixation of pathologic response could be obtained by selection of donors (Walter et al., 1963). In the hands of Burmester et al. (1959b), even so-called "pure" strains of erythroblastosis (R) and and myeloblastosis (BAI-A), produced all combinations of the oncogenic spectrum, inclusive of "renal carcinoma," with the exception of myeloblastosis and visceral lymphomatosis in the same bird. Both diseases were found to be transmitted also by contact, a property which was formerly attributed only to lymphomatosis.

To test the relationship of RPL-12 to field virus tumors, Burmester and Fredrickson (1964) collected material from 22 widely separated flocks in the U.S. and induced better than 50 per cent neoplasm

mortality in L 15 1 inoculated chickens from 9 sources. According to Burmester (1962) these data pointed to a single causative virus but with minor continuous differences for erythroblastosis, visceral lymphomatosis, osteopetrosis, fibrosarcoma, hemangioendothelioma, and nephroma. Myeloblastosis, myelocytomatosis, and neural and ocular lymphomatosis were not observed, in spite of the fact that some of the donors were so affected.

The latter point as to neural and ocular lymphomatosis was of particular interest in light of the reports by Sevoian and his associates on the experimental reproduction of the neural and visceral form of lymphomatosis in Cornell S-line chicks (Sevoian and Chamberlain, 1962, Sevoian et al., 1962), and the preferential occurrence of these forms in young and in old chickens, respectively, as seen in the field (Sevoian and Chamberlain, 1963). In their opinion (Sevoian et al., 1963a) these points furnished new support for the etiologic unity of avian lymphomatosis.

In contrast to the above neoplastic concept of lymphomatosis, Campbell (1954, 1956), Darcel (1957), and Chubb and Gordon (1957) interpreted the term lymphomatosis as representing a chronic inflammatory condition, with neural, ocular, or visceral localizations. Neoplastic aberrations of the lymphoid series were designated as lymphoid leukosis. Histogenetic considerations formed the primary basis of differentiation. To avoid confusion between inflammatory lymphomatosis and neoplastic lymphoid leukosis, the former designation was to be dropped and replaced by Marek's disease (Biggs, 1961). Unfortunately this term is little understood in this country.

Myelocytomatosis. Aleukemic myeloid leukosis was considered by Ellermann (1923) as a subvariety of transmissible myeloid leukosis. The disease was ordinarily associated with tumor formation. Pentimalli (1915) apparently first described a spontaneous chicken tumor which was composed almost exclusively of myelocytes with the characteristic granu-

lations of the mature eosinophil and heterophil. Mathews (1929), believing the tumor to be analogous to chloroma in man, suggested the term leukochloroma. He failed to show transmissibility of the condition. Feldman (1932) regarded it as a definite neoplastic process which he classified as myelocytoma. In a passage experiment with lymphomatosis strain 2, Furth (1933) observed cases of myelocytoma with myelocytic blood involvement (myelomatosis). This apparently constitutes one of the few recorded instances of transmissible myelocytomatosis.

Nephroblastoma. This tumor was formerly known as embryonal nephroma, resembling the Wilm's tumor in man and was considered to represent a developmental aberration. Recently it has been produced with certain strains of leukosis virus.

Carr (1956) first reported the induction of renal adenocarcinoma with Engelbreth-Holm's ES1 strain of erythroblastosis. Only chicks inoculated intramuscularly under 2 weeks of age manifested this lesion about 4 weeks later. Survivors over 3 weeks old (Carr, 1959) had occasionally true, transplantable metastases. Among many other tumor viruses tried, only the MH2 Murray and Begg reticuloendothelioma strain had a similar oncogenic attribute. The author pointed out that this was the second case of a mesenchymal virus attacking immature kidney tissue which is of mesodermal origin.

In long range experiments with established erythroblastosis (R) and myeloblastosis (BAI-A) strain, Burmester et al. (1959a) observed the latter to produce not only myeloblastosis, but also visceral lymphomatosis, renal carcinoma, and osteopetrosis. Subsequently, Walter et al. (1962) studied the transmission and pathology of this virus-induced tumor. He proposed the term nephroblastoma as a more accurate designation to indicate that primitive nephrogenic tissue is capable of differentiating into both epithelial and connective tissue. By transplantation it was possible to alter the oncogenic potenti-

alities of the BAI-A strain to an almost "pure" nephroblastoma strain. Pathologically, nephroblastoma is essentially composed of malformed nephrons with occasional admixtures of cartilaginous and osteoid tissue. In trying to explain this biologic response de Thé et al. (1962) assume that the myeloblastosis virus acts in the differentiation of nephrogenic cells like a normal inductor, but with abnormal results. The detailed morphologic studies of Ishiguro et al. (1962) have shown that the growth originates in nephrogenic elements which are residual in the postembryonic kidney of the fowl.

The unitarian view. In general the extended investigations of the avian leukoses by Furth tended to show that each transmissible strain represents an etiologic unit because of its more or less definite, if occasionally wide [e.g., strain 2 (Furth, 1933)], pathologic range. Quite in contrast to this concept is the unitarian point of view which assumes that a single etiologic agent is responsible for all of the various pathologic manifestations of the avian leukosis complex. On the basis of transmission experiments with neurolymphomatosis and fowl leukosis, Patterson and co-workers (1932, 1931, 1936) concluded that "fowl leukosis" can be subdivided into erythroid, myeloid, lymphoid (including lymphocytoma), nerve, eye, and mixed types, all of which were considered to be different expressions of the same transmissible disease.

Johnson (1931), in continuation of his work on lymphomatosis (1932), considered erythro- and myeloleukosis likewise to be due to the causal agent of lymphomatosis, and suggested the inclusive term hemocytoblastosis. This term was based upon the concept of Jordan and Johnson (1935) and Jordan (1936) that the hemocytoblast of the marrow stroma is the primitive reticulum stem cell which gives rise to both the erythroblastic and granuloblastic series. This was in conformity with Ringoen (1931), and in contrast to the theory of attributing erythrogenesis to the endothelial cells of the venous sinuses, advanced

by Doan et al. (1925). Hall and associates (1941, 1943) developed a strain of hemocytoblastosis from original neurolymphomatosis material which, in the hands of the U.S. Regional Laboratory workers, showed the characteristics of myeloblastosis (RPL-1).

Emmel (1939) also advanced a unitarian view and likewise used the inclusive term hemocytoblastosis for an increase or decrease in leukocytes accompanied by the appearance of immature and degenerative blood cells in the circulating blood. Blount (1939) has shown that similar blood pictures occur in physiologic transition stages from embryonic to adult life and in various unrelated diseases.

Relation of leukosis to virus tumors. Leukosis was thought to be unrelated to transmissible sarcomas and similar tumors of the fowl which have been studied extensively by Rous, his associates, and other workers (for ref. see Claude and Murphy, 1933; Foulds, 1934). Oberling and Guérin (1933a, b), however, presented evidence on the production of malignant tumors of the Rous type with the virus of transmissible leukosis; a similar polyvalent strain was studied by Rothe-Meyer and Engelbreth-Holm (1933) and by Engelbreth-Holm and Rothe-Meyer (1935). A strain of leukosis described by Jármai (1935) produced fibrosarcomas at the point of injection in leukosis-refractory birds.

These observations stimulated a large amount of investigational work on the relation of leukosis to sarcoma, the results of which seemed to indicate that simple, mixed, and complex strains occur (Furth, 1936a).

Simple or pure strains maintain their pathologic identity in successive passages, as exemplified by the Rous sarcoma or erythroleukosis (strain 1) of Furth (1931a), which Stubbs (1938) tested for tumor-producing properties over several years, with negative results. A recently isolated Canadian strain of erythroleukosis likewise failed to produce neoplasm at the site of inoculation (Wickware, 1943, 1946).

If leukosis and sarcomalike processes occur in the same donor and prove to be dissociable in subpassages, the conception of "mixed" strain is applicable. Furth (1936b) observed an osteochondrosarcoma (strain 12) in a bird inoculated with lymphomatosis (strain 2) (Furth, 1933) and showed that in successive transplantations both pathologic components occurred either alone or in combination. However, later culture studies of the virus in vitro by Furth and Breedis (1935) suggested that it may have been a complex strain. From a spontaneous ovarian tumor which had both lymphomatous and sarcomatous characters, Jungherr (1937) developed agents of lymphomatosis and sarcomatosis, the latter of which was carried as such through many subpassages by Cole (1941).

Complex strains apparently are due to a single agent which can stimulate both primitive blood cells and fibroblastic cells. Stubbs and Furth (1935) described the interesting strain 13 which produced sarcoma on subcutaneous or intramuscular inoculation, and diffuse endothelial sarcomatosis in the blood-forming organs associated with erythroleukosis, when injected intravenously. The strain studied by Oberling and Guérin (1933a, b), Rothe-Meyer and Engelbreth-Holm (1933), and Jármai (1935) may have been of a similar order (Furth, 1936a).

A major impetus has come from the observations of Duran-Reynals (1940, 1941, 1947) that the classical Rous sarcoma virus is capable of assuming hemorrhagic, neurotropic, and osteopetrotic properties, after experimental passage through newly hatched ducks and chickens. These findings suggested a necrotizing effect of the virus on the vascular endothelium, but Carr (1962) believed that the "hemorrhagic disease" induced by Rous virus 1 and other avian tumor viruses, tested by him, was primarily associated with pre-existing foci of extramedullary hematopoiesis and not in itself evidence of a viral necrotizing property. In studying the genetic resistance of fowls to Rous sarcoma virus, Greenwood and Carr (1951) obtained increased resistance to artificial

sarcoma infection only at the expense of an increased death rate from fowl paralysis, and suggested combined consideration of the sarcoma-leukemia-fowl paralysis viruses.

In a comprehensive review of the role of viruses in the production of cancer, Oberling and Guérin (1954) pointed out that even malignant tumors which are clearly related, such as the Rous and the Fujinami sarcomas, are distinguishable, since morphogenesis may be a consequence of the narrow cytotropism of the viruses involved. The authors had no doubt as to the basic leukemic nature of the various forms of avian lymphomatosis and believed many closely related viruses to be involved. Beard (1957a) has summarized the evidence for the relationship of avian leukosis to avian sarcomas, particularly on the basis of cross virus neutralization tests. He believes that preliminary studies warrant the interpretation of an etiologic interrelationship between various forms of the leukosis complex and certain avian tumors. Clarification of the etiology can come only from the application of modern virologic techniques which are available, but "failure of cell-free transmission cannot be accepted as evidence that a given tumor is not of viral etiology" (Beard, 1957b).

Research on Rous sarcoma virus has recently entered entirely new territories. Following the original demonstration of the pathogenicity of Rous virus for albino rats by Svet-Moldavsky (1957; with Skorikova, 1960) and Zilber and Kryukova (1957), Ahlström et al. (1963) reported the transmissibility of the Schmidt-Ruppin strain to young rats, mice, guinea pigs, and rabbits, whereas the Mill Hill strain did not induce such tumors, although these strains showed serologic relationship by cross protection tests. Takes in young rhesus monkeys were first obtained by Munroe and Windle (1963). By intravenous inoculation of a "standard" Rous virus strain, Burmester and Walter (1961) were able to induce not only the expected disease, but also visceral lymphomatosis and erythroblastosis. With Fontes, they (Burmester

et al., 1960b) even obtained evidence of Rous sarcoma transmission by contact, an observation not previously recorded. However, the authors did not consider this as critical evidence for a single multipotent virus because of a possible mixture of viruses in the starting inoculum. This possibility was recently confirmed by Rubin and Vogt (1962) who found the high-titer Bryan strain of Rous sarcoma virus to contain also the Rous associated virus which has the physical and biologic attributes of the lymphomatosis-myeloblastosis agents.

In a recent survey of avian virus growths and their etiologic agents, Beard (1963a) emphasizes that these tumors are all of mesodermal origin and are characterized more by the growth potential of the cell involved than by the virus. Avian tumor viruses are genetically unstable: their responses are affected by experimental adaptation and spontaneous mutation. With particular reference to the avian leukosis complex, he (1963b) points out that transmission of leukosis material results in a large variety of conditions, but that similarities in biologic characters of solid and hematopoietic tissue tumors reveal their etiologic interrelationship. He takes issue with the details of data collected over the past half century which have created the illusion of complexity, and questions whether any strain can ever be designated as "the virus" of lymphomatosis because the latter is essentially a pathologic entity.

Nomenclature. The boundaries of the disease group are indistinct. In the restricted sense, *the avian leukosis complex includes primarily those diseases which are characterized by autonomous proliferation of essential blood-forming cells.* This definition may have to be extended to include viral tumors derived from the mesodermal layer of the embryo, including the hematopoietic, connective, bone-forming, endothelial, and mesothelial tissues and certain epithelial cells of kidney and ovary (Beard, 1963b). The common features for this disease group, according to Beard (1957a), are that each form represents a

pathologic entity; combinations of these forms may occur in nature in the same flock or bird; various mixtures can be transmitted by cellular or filtered material; and, most inexplicably, certain forms may be obtained from source materials which do not show the original pathologic features.

A tentative pathologic classification, without implying etiologic unity, was suggested by a committee (Jungherr et al., 1941) cooperating with the United States Regional Poultry Research Laboratory, East Lansing, Michigan. The various forms of the disease complex, which were understood to occur in leukemic, subleukemic, or aleukemic variety, were grouped into lymphomatosis, with either neural, ocular, visceral, or osteopetrotic localization; erythroblastosis; granuloblastosis; myelocytomatosis; and sarcomatosis.

Beard (1957a) conceived the avian leukosis complex as a group of diseases, with lymphomatosis and its neural, ocular, and visceral localizations on the one hand, leukemias and sarcomas on the other, and osteopetrosis as a potential link between the extremes of the pathologic spectrum (Fig. 19.1).

Chubb and Gordon (1957) suggested a modified conception, based upon the histogenetic interpretation of Campbell (1954). Leukosis was divided into erythroleukosis; myeloid leukosis of diffuse or discrete distribution, the latter identical with myelocytoma; and lymphoid leukosis again of diffuse or discrete distribution,

FIG. 19.1 — The major conditions of the avian leukosis complex. The connecting curves indicate, in part, the diversity of combinations occurring naturally, or transmissible by experimental means. (Beard, 1957a, Ann. N.Y. Acad. Sci.)

the latter identical with lymphocytoma. Lymphomatosis was divided into visceral, neural, and ocular forms. Osteopetrosis was placed into a separate category. The term lymphomatosis in the above sense has since been replaced by Marek's disease (Gordon, 1960; Campbell, 1961; Biggs, 1963). However, the distinction between inflammatory and neoplastic forms is not tenable because of the limitations of the histopathologic approach. Although much has been written about classification, the greatest need is for large scale critical experiments to show whether control measures against known agents such as RIF will alter the susceptibility of a flock to agents which may be implicated in Marek's disease.

A simplified modification (with scientific and common equivalents) of the 1941 proposal has been suggested by Cottral (1952) and is used here. It comprises, neural, ocular, and visceral lymphomatosis, osteopetrosis, erythroblastosis, myeloblastosis, and myelocytomatosis. To this has to be added nephroblastoma. It has the advantage of designating the individual pathologic forms, and thereby avoiding any implication as to etiologic unity.

In rendering a diagnosis emphasis should be placed upon stating the specific form or forms found and preferably also the method of arriving at such diagnosis, rather than generic or group designations such as lymphomatosis or avian leukosis complex.

NEURAL LYMPHOMATOSIS

Synonyms. Fowl paralysis, range paralysis, polyneuritis (Marek, 1907), neuritis (Doyle, 1926), neurolymphomatosis gallinarum (Pappenheimer et al., 1926), neurogranulomatosis (Lerche and Fritzsche, 1934), Marek's disease (Biggs, 1961).

Paretic symptoms may be observed as accompanying a variety of diseases such as tuberculosis, staphylococcosis, fowl cholera, helminthiasis, coccidiosis, botulism, avitaminosis, lead and salt poisoning, etc. To differentiate such conditions from true fowl paralysis, as discussed below, the for-
FIG. 19.2 — Neural lymphomatosis. Typical clinical position in advanced case. (L. P. Doyle, Jour. A.V.M.A.)

mer may be grouped under the term symptomatic paralysis, according to Bayon (1932).

Occurrence. The disease has been observed in every major poultry-producing country of the world. It attacks primarily young birds between 2 and 5 months of age, but has been seen as early as 3 weeks of age and as late as the second year of production. All breeds and both sexes are susceptible. The losses are variously estimated from 5 to 25 per cent in affected flocks. Under practical conditions the disease often makes its appearance when the birds are first turned out on range; then, after a period of quiescence, the disease apparently resumes its course in the visceral form when the birds are put into the laying houses.

Symptomatology. The clinical signs of the disease are usually those of asymmetric progressive paresis of the leg, wing, or neck, the paresis being either spastic or flaccid in character. In the beginning the affected leg may show inward curving of the toes, weakness, or incoordination. Later on, the bird has a tendency to hold one foot stretched forward or backward, a position which is quite characteristic (Fig. 19.2). If both legs are affected the animal moves with difficulty, in a squatting position. Involvement of a wing is indicated by drooping of the extremity (Fig. 19.3); if one tries to spread the wings the dis-

FIG. 19.3 — Involvement of a wing, as indicated by drooping of extremity. (L. P. Doyle, Jour. A.V.M.A.)

eased one often gives the impression of increased resistance. Paresis of the neck may be suggested by low carriage of the head and incipient torticollis; affection of the deep muscles and the nerves, especially the vagus, may lead to dilatation of the crop and gasping symptoms. Durant and McDougle (1945) considered soiled, damp, "front" feathers under the beak and along the throat to be a sign of neural lymphomatosis and attributed it to involvement of the posterior cranial and the anterior cervical nerves. Locomotory disturbances are often associated with systemic reactions such as loss of weight, paleness, anorexia, and diarrhea, although the appetite not infrequently remains good. The signs of true fowl paralysis are not specific and vary widely in intensity.

Pathology. The gross anatomic features of the disease are characterized by localized or occasionally diffuse grayish, soft swellings of the peripheral nerve trunks. The femoral portion of the sciatic trunk is commonly affected (Fig. 19.4A). This nerve can be observed easily by lifting up the large triangular adductor muscles on the median surface of the thigh under which its two strands run parallel with the femoral artery. The normal nerve is uniform in width, white, and cross-striated. Loss of striation is suggestive of the disease. Bilateral comparison permits the detection of mild alterations. For detailed examination the distal and proximal ramifications of the nerve should be exposed. Changes may be seen in the intrapelvic part of the trunk, the so-called sciatic plexus, which originates from four spinal roots and is located under the middle lobe

FIG. 19.4B — Experimental neural lymphomatosis of brachial plexus. (Courtesy Dr. M. Sevoian, University of Massachusetts.)

of the kidney. The lumbar and celiac plexuses stand out very prominently, if affected. Some portion of the brachial plexus may be involved, although there is no constant correlation between neuromuscular disturbances and regional nerve lesions. Vagus affection is apt to occur if respiratory signs are present. The dorsal ganglia of the peripheral nerves, especially in the region of the brachial plexus roots, often undergo grayish enlargement which may extend into the spinal cord and form tumorlike masses (Fig. 19.5). It is of great interest that, after years of trials by other investigators, Sevoian et al. (1962) succeeded in reproducing such lesions by the intraperitoneal inoculation of day-old chicks from the Cornell S-line, with field lymphomatous tumors (Fig. 19.4B).

In uncomplicated cases of fowl paralysis the visceral organs appear normal. The spleen is usually of normal size; the thymus lobes may show glandular enlargement (Jungherr, 1933). According to Johnson (1934) the bone marrow of the ulna and radius, which ordinarily is fatty and aplastic in mature birds, may revert to a

state of hyperactivity often seen in young normal birds.

Systemic lesions were described by Blakemore (1939) and Blakemore and Dalling (1939), who, in transmission experiments of neurolymphomatosis with liver emulsions, observed whitish, ill-defined areas especially in the heart and liver substance corresponding microscopically to focal necrosis followed by infiltration with various mononuclear cells. Typical nerve lesions developed in protracted cases. Glover (1940) made similar observations in chicks experimentally inoculated with neurolymphomatosis from pheasants. Asplin (1944) made the interesting observation that a "chick disease" of known viral etiology was amenable to sulfonamide therapy. In further studies Asplin (1947a) failed to substantiate any etiologic connection with lymphomatosis (1947b) and may have been dealing with the Gal (Gallusadenolike) virus (Burmester et al., 1960d; Sharpless and Jungherr, 1961).

Campbell (1956) advanced the view that the initial change in the liver is focal, fibrinoid necrosis followed by re-
FIG. 19.5 — Neural lymphomatosis. Formol portion of right sciatic nerve thickened. (F. D. Patterson, Iowa State University.)

FIG. 19.6 — Neural lymphomatosis. Section of sciatic nerve. (Poppenheimer, Storrs Agr. Exper. Sta., Bul. 143.)

active lymphocytic infiltrates.

On microscopic examination affected nerves present either follicular or diffuse infiltration with mononuclear cells (Fig. 19.6). The majority of the pathologic elements are indistinguishable from lymphocytes in the circulating blood and correspond to so-called small round cells; others have the character of plasma cells, large mononuclears, or histocytes. The lesions may be associated with edema, myelin degeneration, and reactive increase of the Schwann sheath cells, but axonal degenerations are rare. Spinal and sympathetic ganglia undergo similar infiltrative changes. The disease also affects the central nervous system where it brings about either compact perivascular rings of small densely staining lymphoid cells or submiliary nodules composed of such cells and paler elements, probably of glial origin (Pappenheimer et al., 1926). Granulocytic reactions are not characteristic. The intensity of the central nervous system lesions seems to vary inversely with their development in the peripheral nerves. Ordinarily, involvement of the central nervous system is secondary to that of the peripheral, but one has to recognize the occurrence of a "central" variety of neural lymphomatosis not associated with peripheral nerve lesions. In a recent case of "torticollis," the auditory nerve presented the principal lesions. Siller (1960) described an unusual case of persistent cloacitis (vent gleet) which was characterized by megacolon, typical gross changes in the accompanying intestinal nerve, and microscopic changes in the central nervous system.

Microscopic lesions frequently occur in grossly normal-appearing nerves. Microscopic examination thus constitutes the most sensitive method of diagnosis available at the present time. Due to the focal distribution of the lesions, the accuracy of the method is proportional to the number of levels of the nervous system examined. In a detailed study of lymphoid tissue in some splanchnic nerves, Oakberg (1950) found all of the birds over 20 days

of age in his material to show some basic microscopic lesions and believed them to indicate specific infection.

The intensity of the lesions and their stage of development in the peripheral nerves are variable as brought out by Wight (1962a) who recognized three types, i.e., cellular infiltrations with mature lymphocytes, edema with less cellular infiltration, and lymphoblastic infiltration with mitoses. The second type was most common. In a companion study of the central nervous system, he (1962b) found perivascular cuffs also in the controls and cautiously considered such lesions as an adjunct to the pathologic picture of fowl paralysis. Lymphoblastic infiltrations were often associated with neoplastic disease. There was no evidence of primary neuronal nor myelin degeneration.

Electron microscopic study of the peripheral nerves by Deutsch and Siller (1961) largely confirmed the histologic observations but also disclosed an endoneural fibrosis which may be the pathologic substratum of the clinical signs.

Hematology. In a basic publication Pappenheimer et al. (1926) stated that, although the blood was not subjected to a systematic study, no indications of significant blood changes were observed. Absolute and relative lymphocytosis was noticed by Bayon (1931) in four acute cases. Johnson and Conner (1933) reported an absolute increase in leukocytes, a relative increase of monocytes and basophils, and the appearance of "budded" lymphocytes. Observing an early polymorphonuclear and late lymphocytic leukomorphonuclear and late lymphocytic leukocytosis, Seagar (1933) made this the basis of the so-called cyto-diagnosis of fowl paralysis. Blount (1934), Dobson (1934), Hamilton (1934), and Blakemore (1934) pronounced this test unreliable and nonspecific. Gibbs (1934) confirmed the observations of Seagar, but considered the blood changes of little diagnostic assistance, on account of normal hematologic irregularities. In his pathologic characterization of fowl paralysis, Furth (1935) pointed out the usual lack of blood and bone mar-

row involvement. Jungherr (1934) made serial hematologic examinations of experimentally injected and control birds; the mild evidence of leukocytosis and lymphocytosis found in affected birds was regarded to be statistically insignificant.

Differential diagnosis. Other morbid conditions summarized under the term symptomatic paralysis (Jungherr, 1942) may be accompanied by paretic signs. In questionable cases the specific diagnosis of neurolymphomatosis rests upon the microscopic demonstration of the pathognomonic lesions in the peripheral nerves Brooder chicks may show in the sciatic trunks, as in other organs, slight granulocytic mononuclear foci which are probably expressions of ectopic hematopoiesis and of no diagnostic significance. Neuromalacia, or ariboflavinosis, is characterized by bilateral diffuse graying swelling of the sciatic trunks, which on microscopic examination exhibit severe myelin degeneration and occasionally mild perivascular proliferation of the adventitial cells (Phillips and Engel, 1938). The microscopic lesions of central neurolymphomatosis and avian encephalomyelitis (Jones, 1934) are similar in character except that the latter have a special predilection for the gray matter in the brain (Jungherr, 1935). The "crooked-toes" condition described by Norris et al. (1940), apparently related to mechanically unsuitable floors, is not associated with nerve alterations. Intracranial gliomas may occasionally give rise to paralytic signs (Jungherr and Wolf, 1939). The principles involved in the neuropathologic differentiation of symptomatic paralysis in fowl have been summarized by Jungherr (1953).

Neural Lymphomatosis in Other Species

A disease pathologically indistinguishable from the corresponding condition in the common fowl has been observed in pheasants by Jungherr (1939) (Fig. 19.7). An unusual feature was the finding of localized areas of muscle degeneration, especially in the flexors of the leg, which led to macroscopic "tigering" of the affected muscle and microscopic Zenker's degeneration associated with regenerative phenomena (Fig. 19.8), similar to the muscle changes sometimes observed in young chickens by Potel (1938). Harriss (1939) and Johnson (1941) apparently transmitted fowl paralysis to pheasants. A similar affection of both neural and muscular tissues has been described in turkeys
FIG. 19.7 — Neural lymphomatosis in pheasants. Section of sciatic nerve.

FIG. 19.8 — Neural lymphomatosis in pheasants. Section of leg muscle showing Zenker's degeneration.

by Andrewes and Glover (1939), who regarded it as representing true fowl paralysis in another species of bird. Glover (1940) transmitted turkey paralysis to chicks and believed it to be caused by the same agent which is responsible for chicken paralysis. Sevoian et al. (1963a) found two flocks of turkeys of which the poults were just as susceptible to the lymphomatosis virus as the S-line chicks. In turkeys the spontaneous disease must be differentiated from occasional cases of neurofibromatosis (Helmboldt and Frazier, 1962). Aside from chickens and turkeys, Wight (1963) quoted reports from the literature on neural lymphomatosis in pheasant, pigeon, duck, goose, canary, budgerigar, and swan. He himself observed the disease, associated with lymphoid leukosis, in Japanese quail (Coturnis coturnis japonica) which had been raised near infected fowl. Cottral and Winton (1953) found, in ducks, a condition simulating neural lymphomatosis.

OCULAR LYMPHOMATOSIS

Synonyms. Blindness, gray, glass, pearly-, fish-eye, iritis (Pappenheimer et al., 1926); epidemic blindness (Findlay and Wright, 1933); uveitis (Doyle, 1928); Marek's disease (Biggs, 1961).

As already noted, Kaupp (1921), Doyle (1926), and Pappenheimer et al. (1926) have observed the frequent association of blindness with cases of neural lymphomatosis. Findlay and Wright (1933) and Jaensch and Lerche (1933) believed epidemic blindness to be an expression of fowl paralysis. Similar epizootiologic observations were made by De Boer (1934a, b) in Holland, and Magnusson (1935) in Sweden. Although Upp and Tower (1936), on the basis of crossbreeding studies with paralyzed and blind birds, regarded blindness as an independent disease, later studies by McClary and Upp (1939) showed a high incidence of iritis in the progeny of iritis-affected parents. Bayon (1936) gave a pathologic description of a primary iridocyclitis in fowl said to be distinct from ocular lymphomatosis. Starting with affected iris material, Jungherr (1937) apparently developed transmissible strains of neuro-visceral lymphomatosis. Probably the most elaborate breeding experiments with birds, of which either one or both parents had ocular lymphomatosis, were carried out by Lee and Wilcke (1941), who found that the offspring showed a significantly higher incidence of various forms of the avian leukosis complex than that of nonaffected control

stock. Nelson and Thorp (1943) found pearl-gray irises with irregular pupillary borders to be extensively infiltrated with lymphocytes. They believed the early stages of the disease, without pupillary changes, to be represented by depigmentation and vascular congestion of the iris. Using chicks from iritic dams as virus donors, Durant and McDougle (1945) transmitted neural lymphomatosis by direct blood transfusion to susceptible chicks.

On the other hand, Ball (1944), working with Single Comb White Leghorns, found depigmentation of the iris, with round regular pupils, to be common and due to various factors such as lack of, or the presence of inhibitors of, carotenoid pigments in the diet, and high egg production A large proportion of such depigmented irises showed lymphocytic infiltration on microscopic study (Ball, 1945). Breeding from birds so affected failed to indicate a significant relationship between iris color of the dam and mortality from neoplastic or other diseases in her progeny (Ball and Cole, 1946). Nelson (1947) likewise believed that ocular lymphomatosis should be diagnosed by criteria other than depigmentation

The suggestion by Bullis et al. (1950) that ammonia fumes arising from deep litter in poorly ventilated brooder houses may cause eye lesions not readily distinguishable from ocular lymphomatosis, and their experimental production in the reviewer's laboratory by Ellis and Winn (1950) and by Faddoul and Ringrose (1950), throw doubt upon the occurrence

FIG. 19.9 — Ocular lymphomatosis. The eye on the left shows annular, that on the right, spotty, depigmentation of the iris.

of ocular lymphomatosis in young birds. Pathologically these so-called ammonia burns resemble the primary iridocyclitis described by Bayon (1936) but usually show the added feature of epithelial defects in the cornea. With the recent recognition of iritis and cataract as a possible sequence to avian encephalomyelitis (epidemic tremor) by Peckham (1957) and Bridges and Flowers (1958), this malady should be considered in differential diagnosis. Rigdon (1959), however, found also such cataracts in chickens with lymphomatosis.

Occurrence. Ocular lymphomatosis occurs primarily in flocks affected with the neural form but, on the whole, somewhat later during the life of the birds, primarily during early maturity. Accurate differential diagnosis is important. Variations in incidence are not considered as a dependable sign of the prevalence in the flock of other manifestations of the avian leukosis complex.

Symptomatology. Familiarity with the signs is necessary for those concerned with selection of breeding birds. Refinements in clinico-diagnostic methods, perhaps with the aid of an ophthalmoscope, should be helpful.

In the normal eye the iris has either a clear bay or orange color; the pupil is circular and has the power of ready accommodation to light intensity. The iris sometimes shows fine radial lines or clefts, which are probably in the nature of congenital defects

Ocular lymphomatosis manifests itself by concentric annular or spotty depigmentation or by diffuse bluish-gray fading of the iris in one or both eyes (Fig. 19.9). The pupil becomes irregular to the extent of showing angular indentations and gradual loss of light accommodation. In advanced stages the iris presents a diffuse grayish opacity with pin-point pupil (Fig. 19.10). The anterior chamber of the eye sometimes contains slightly turbid exudate which leads to increased convexity of the cornea as in glaucoma.

Pathology. The specific pathologic fea-

FIG. 19.10 — Ocular lymphomatosis. Uveitis causing total blindness. (L. P. Doyle, Jour. A.V.M.A.)

tures of the disease can be demonstrated only by histologic methods. Both eyes and brain should be examined. The iris is most frequently affected and shows mononuclear infiltrates usually consisting of small round cells occasionally mixed with large polyblastlike cells (Fig. 19.11). Exclusive infiltration with heterophils is not characteristic, and raises the question of traumatic ophthalmitis. The anterior chamber of the eye may contain granular or amorphous material (Fig. 19.12); actual cellular exudate is rare. The bulbar lesions may extend into the eye muscles, especially the *rectus lateralis* and *ciliaris*. In a comparatively small number of cases, lesions

hepato-lymphomatosis (Furth, 1935), lymphosarcoma, lymphocytomatosis, certain endothelioma (Furth, 1933), lymphosarcomatosis (Burmester, 1957a), inflammatory type, Marek's disease, neoplastic type, lymphoid leukosis (Campbell, 1961).

The difficulties in defining the term visceral lymphomatosis have been discussed. Papers on fowl paralysis by Oakley (1935), Dalling and Warrack (1936), Harriss et al. (1947), Gildow et al. (1940), and others seem to have used the term lymphomatosis in the present sense. A conference of research workers (Burmester et al., 1959c) considered visceral lymphomatosis to be a broad term for neoplasia of the lymphocytic series, with lymphoblastomatosis and lymphocytomatosis to express respective degrees of cellular differentiation.

Occurrence. There hardly can be any doubt that under the conditions of modern intensive poultry production, visceral lymphomatosis represents the most common type of avian neoplasia. Highly instructive epizootiologic data have been presented by Blaxland (1956) and Chubb and Gordon (1957). In the average flock the occurrence goes parallel with the neural and ocular forms. However, one gains the impression that the visceral form occurs somewhat later than the nerve or eye type, especially during the laying period of pullets. The malady has been recognized as early as the fourth week of the brooding period. The extreme affections of the liver, so-called hepato-lymphomatosis (Furth, 1935) seem to be reserved for mature pullets or hens.

Of great interest is the increased incidence of visceral lymphomatosis in broilers, observed by Benton and Cover (1957). A recent survey of the disease at processing by Benton et al. (1962) in broilers from Delmarva and Georgia brought out the extreme variations from flock to flock both in total incidence and in the gross lesions presented, with skin and visceral lesions predominant in the female, and osteopetrosis in the male. The occurrence of the disease in turkeys is well established by the reports

of Simpson et al. (1957) and Newberne and Vosbrink (1958). Experimental propagation has been possible by cellular transplants (Belding and Sanger, 1961).

Symptomatology. The outward signs of the disease are indefinite. The comb becomes pale and shrivelled, occasionally darkened to the point of cyanosis in liver involvement. The signs may be accompanied by loss of appetite, loss of flesh, or diarrhea. Widespread attack of the mesentery can result in secondary ascites ("abdominal dropsy") and cause changes in contour and posture, spoken of as "penguin position." In systematic culling, sufficiently thin birds permit palpation of certain internal organs; thus, enlargement of the liver may be recognized by its projection beyond the metasternum and caudal margin of the ribs. The condition is often of long standing, but the observed clinical course may be quite short in that seemingly healthy birds succumb within a few days.

Pathology. Probably no other disease of birds presents a greater variety of gross pathologic pictures than visceral lymphomatosis. The large abdominal glands, such as liver and kidney, are principally affected, but there is really no organ of the body, including the skin, which is not implicated at times.

In a consideration of the gross alterations, one might commence with the spleen, because this organ is characteristically enlarged, in most cases, up to three times the normal size. Splenic hyperplasia, however, may terminate in exhaustion and atrophy. The affected spleen is usually of a grayish-brown color associated with milky thickenings in the capsule. Cross section exhibits minute grayish areas which correspond to hyperplastic lymphocytic aggregates. Instead of such diffuse changes, the spleen may present circumscribed projecting grayish tumors.

In the liver, lymphomatosis likewise manifests itself in a "diffuse" and a "nodular" variety, according to Feldman (1932). Both may be present in the same specimen. In the former variety, which is the more

common, the liver is enlarged to various degrees, grayish, and of granular surface (Fig. 19.13). The gray background is often relieved by red lines or dots of congested vessels which give the liver a characteristically *marbleized appearance*. In the nodular variety there is less enlargement, but the parenchyma is studded with firm grayish tumors of various sizes, which, unless confluent, are spherical except for surface flattening. On section these tumors are firm, smooth, lardaceous, and rarely show necrobiotic changes.

Implication of the gonads, especially in the female, has been stressed repeatedly (Pappenheimer et al., 1926). The immature ovary may show nothing more than diffuse coarse granular hyperplasia, while the producing organ exhibits alternating normal and tumorous egg follicles.

FIG. 19.13 — Visceral lymphomatosis, diffuse variety. The liver is markedly enlarged, grayish, and of granular surface. (Iowa State University.)

Extensive affection is indicated by cauliflowerlike tumors with multiple pedunculation. That such ovarian involvement may proceed at a rapid pace is indicated by birds which were observed to have a monthly trap nest record of twenty-four eggs one month prior to death from ovarian lymphomatosis. Male gonads are sometimes subject to lymphomatous affection, the disease having been diagnosed as early as the fourth week of age. Marked differences in the size of the testicles should arouse suspicion of the disease, which can be confirmed microscopically. Veritable tumor formation in the testicles is rare.

Among other internal organs the kidneys are often involved, primarily by diffuse grayish enlargement of some of the three major lobes, although nodular tumor formations occur at times. Due to the decrease of the renal secretory surface, affected kidneys may show secondary nephritic changes of the nonaffected lobes. Without concomitant lymphomatous alterations, these kidney lesions may be difficult to differentiate from uremic nephritis (visceral gout).

The heart shows gross changes more *frequently than is realized*; there occur either grayish striations (tigering) in the epicardium, or prominent myocardial tumors which lead to deformities and local adhesive pericarditis; at times, the bicuspid valve presents small tumorous nodules. The lymphomatous process is also apt to originate in or spread to adjacent organs such as the proventriculus, gizzard, and lungs (Fig. 19.14). Multiple tumors are often implanted in the mesentery and peritoneum, recalling the appearance of "pearl disease" in bovine tuberculosis. In such cases there is apt to be serous transudation into the abdominal cavity. Oviduct and mesosalpinx are comparatively refractory.

The glands of the head and the skin are subject to attack by the process. Unilateral swelling of the cheek, as in "roup," may be due to lymphomatosis of the nasolacrimal glands. Affected integument exhibits small multiple tumors of the feather

FIG. 19.14 — Visceral lymphomatosis. Marked tumorous involvement of both lungs. (F. D. Patterson, Iowa State University.)

follicles or large skin tumors prone to superficial ulceration. Skin involvement often escapes detection until the birds are dressed. Helmboldt *et al.* (1963) studied 44 cases of skin leukosis in condemned 9-week-old broilers and found the majority to be associated with brain, spinal cord, and peripheral nerve lesions, in falling order. Some of the controls also presented brain lesions.

The condition of the bone marrow is ordinarily analogous to that described in neural lymphomatosis (Johnson, 1934), but frank leukemic cases of lymphomatosis may show minute grayish tumors (Furth, 1933).

Endothelioma apparently is a rare type of tumor in visceral lymphomatosis. It was first described as a transmissible condition in the fowl by Begg (1927), and again observed in transmission experiments of lymphomatosis by Furth (1933), Jungherr (1937), and Burmester (1957b). Gross combinations of edematous grayish and hemorrhagic tumors should make one suspect an endotheliomatous process; the specific diagnosis rests upon microscopic study.

In contrast to the gross manifestations, the histopathologic picture of visceral lymphomatosis is comparatively uniform. Typical changes are represented by massive accumulations in various organs of proliferating lymphoid cells which are usually much more widely distributed than is suggested by gross alterations. The

FIG. 19.15 – Visceral lymphomatosis. Section of liver showing massive lymphoid infiltration. (Pappenheimer, Storrs Agr. Exper. Sta.)
pathologic elements are represented by two prototypes, namely, so-called small round cells resembling lymphocytes, and large lymphoblastlike cells. Between these extremes lymphoma types occur. The small more mature cell type is apt to occur in visceral complications of the neural form and in the extreme cases of liver enlargement (Fig. 19.15), while the large cell type prevails in rapidly growing lymphoid tumors.

Difficulties may arise in the interpretation of microscopic lymphomatous changes. As would be expected, the lesions have a predilection for organs containing normal lymphoid tissue. With the exception of thymus, cecal tonsils, bursa of Fabricius, submucosa of the intestine and of the secondary bronchi, there are no organized lymph nodes in the fowl; but microscopic lymphoid foci are usually present without anatomic regularity in the parenchymatous organs and the digestive tract. These follicles are subject to stimulation, aside from the etiologic agent of lymphomatosis, also by other viral factors (e.g., avian encephalomyelitis). Thus it is

often difficult to state whether a given lymphoid follicle represents normal, reactive, or neoplastic tissue. A guide to interpretation should come from consideration of all the pathologic evidence available in the case. In ordinary fixed tissues the large lymphoblastlike cells are difficult to differentiate from myeloblasts, hemocytoblasts, etc. Special fixing and staining methods designed to bring out the differential characters of hematopoietic elements are of value. Recourse may be made to impression smears or "Klatsch" preparations stained according to Wright and/or Giemsa.

In a series of six detailed papers Lucas and his associates (1949, 1950, 1951) have studied the relation of so-called normal lymphoid foci in the pancreas to lymphomatosis in chicken, turkey, dove, pheasant, wild mallard, and White Pekin duck. They concluded that the amount of ectopic lymphoid tissue was approximately proportional to the predisposition toward lymphomatosis. While the question could not be answered definitely whether these lymphoid foci were actually induced or

only stimulated by the lymphomatosis agent, the report of the United States Bureau of Animal Industry Regional Poultry Research Laboratory (1951) suggested the latter.

A major contribution to the question of lymphoid tissue in chickens on purely anatomical grounds was made by Biggs (1957). He reviewed the work of Kondo (1937) in Japan and confirmed the concept that noncapsulated mural lymphoid nodules occur normally along the lymph vessels which accompany the lymph veins. Dennington and Lucas (1960) reduced significantly the number of ectopic lymphoid foci in the pancreas by intermittent heat treatment during the first 16 days of brooding. They cited these findings in support of the hypothesis that such lymphoid structures are not ontogenetically normal, but the result of a defense reaction.

Regarding the histopathology of individual organs, the spleen in early cases exhibits lymphoid hyperplasia around the "adenoid sheaths," which are the functional equivalents of the Malpighian corpuscles in mammals. The hyperplastic areas become confluent and form broad anastomosing masses in the red pulp. True Malpighian corpuscles are absent in the bird, but organized lymphoid follicles appear irregularly in the normal spleen.

Campbell (1956) claimed differentiation of inflammatory lymphomatosis and neoplastic lymphoid leukosis, in his terminology, by histopathologic means. Similar changes, however, are seen under normal and reactive conditions (Thorbecke *et al.*, 1957).

The liver is often involved in the absence of gross lesions. Miliary lymphoid accumulations appear in the parenchyma or the portal islands. In the latter location, as elsewhere, there is frequently a secondary admixture of metamyelocytes and heterophils, probably because such areas are still endowed with some of their embryonic hematopoietic potentialities. For severe cases massive compact expanses of lymphoid tissue are typical. They are in sharp relief from the surviving liver tissue

by virtue of their basophilic staining affinity. The hepatic parenchyma itself shows only slight damage, a fact which may account for the surprising vitality of some birds in the presence of liver involvement. Horiuchi (1961) recognized the following three histologic types: the nodular one, characterized by fibroid cells which are continuous with the sinusoidal epithelium; the diffuse type in which cellular proliferation takes place along the spaces of Disse; and the infiltrative type which consists primarily of a network of sinusoidal endothelium.

The ovary shows either follicular or infiltrative lymphoid alterations; the latter often encroach upon or engulf ovarian follicles. In the kidney the process exhibits frequently an infiltrative interstitial character; since "interstitial nephritis" is rare in birds, such changes are often an expression of lymphomatosis. The myocardium is particularly susceptible; in the beginning the lesions are infiltrative but later form coherent neoplastic masses. The cardiac muscle of healthy young birds often shows small ectopic foci of lympho- and granulopoiesis (Pappenheimer *et al.* 1929a). Although recognized now as part of the normal histoanatomy of the chicken, it may be these foci which undergo neoplastic degeneration under the influence of the lymphomatosis agent. Sclerosis of the coronary arteries is common in mature birds, but there is an approximate six-fold increase of incidence in chickens exposed to the lymphomatosis agent according to Paterson and Cottral (1950).

Endothelioma is considered to be a possible extension of the microscopic features of lymphomatosis. According to Furth (1934), neoplastic growth of endothelium may occur in any location of normal endothelium, including the liver, spleen, and bone marrow. Quite often these tumors are of purely microscopic size. The architecture is variable and may present solid, glandular, syncytial, and angiomatous types. The tumor is characteristically composed of basophilic cells with large chromatin-poor vesicular nuclei which ex-

FIG. 19.16 — Endothelioma in visceral lymphomatosis. Experimental case. Section of muscle affected with giant-cell endothelioma. (Jungherr, Storrs Agr. Exper. Sta.)
hibit thick nuclear membranes and prominent nucleoli. There frequently occur groups of multinucleated giant cells not unlike the Langhans type in tuberculosis (Fig. 19.16). The tendency toward necrobiotic changes is marked. The diagnosis of endothelioma is strengthened by demonstrating connection with normal endothelium. However, it is often difficult to decide whether the tumor is of endothelial, mesenchymal, or mesothelial origin.

Hematology. Much of what has been stated under this heading in regard to neural lymphomatosis is applicable to the aleukemic cases of visceral lymphomatosis. In other instances the blood picture may show subleukemic or leukemic lymphoid alterations. The term "subleukemic" is used, in accordance with the suggestion of Furth (1933), to indicate a moderate increase of the leukocyte count, up to 100,000 per cu. mm. of blood.

Specific blood changes are either qualitative or quantitative in nature, of which the former deserve special attention; they are often transitory or terminal and, on the whole, less constant than in erythro- and granuloblastosis. Aside from the appearance of "budded" or pseudopoded lymphocytes in increased number, the blood picture may be characterized by the presence of immature lymphocytes in the circulating blood. The degree of immaturity of the leukemic cell varies. According to Furth (1933), in subleukemic forms one observes primarily medium-sized basophilic lymphocytes showing vacuoles and azurophilic granules. The large lymphocyte predominates in frank leukemic cases. Apart from size, these cells are distinguished by a large eccentric nucleus composed of spongy chromatin and a comparatively narrow mass of intensely basophilic cytoplasm. These cells are considered by Furth (1934) to be capable of producing erythroblasts, myelocytes, and lymphocytes and thus correspond to the hemocytoblast in the terminology of Ferrata-Maximow. The lympholeukemic alterations may be accompanied by anemic changes, such as basophilic erythrocytes and erythroblasts; also erythrogonia suggestive of erythroblastosis occur occasionally.

Differential diagnosis. Of other diseases capable of forming tumorlike nodules in the visceral organs, tuberculosis and pullorum disease must be kept in mind. Avian tuberculosis also attacks primarily spleen and liver, but the nodules are usually yellowish, granular on the surface, and readily separable from the parenchyma of the affected organ. Pullorum nodules are

found in the heart of adult birds, particularly males, but as a rule are accompanied by inflammatory and congestive phenomena. In both diseases bacterioscopic and cultural tests can give further clues to the etiologic nature of the pathologic processes.

In turkeys, low grade lesions of histomoniasis in liver and spleen as seen on the inspection line, are suggestive of visceral lymphomatosis but may be diagnosed histologically by their granulomatous character (McKee et al., 1963).

OSTEOPETROSIS

Synonyms. Thick-leg disease, marble bone, akropachia ossea and hyperplastic ostitis (Reinhardt, 1930), hypertrophic osteitis (Reis and Nobrega, 1936), osteodystrophia fibrosa cystica (Gohs, 1934a, b), diffuse osteoperiostitis (Pugh, 1927), Paget's disease (Venkataraman, 1936), osteopetrosis gallinarum (Jungherr and Landauer, 1938).

Hypertrophic osteopathies of the fowl have received occasional mention in the literature (Reinhardt, 1930). Sporadic outbreaks of diffuse osteoperiostitis in male birds have been reported by Pugh (1927) in England, and Venkataraman (1936) in India. Brochet (1935) named several diseases as possibly leading to bone deformities, namely acromegaly, Paget's disease, tuberculosis, gigantism, osteosarcoma and hypervitaminosis; he thought hypertrophic bone changes in birds to be secondary to respiratory infections or endocrine dysfunctions. Campbell (1954) and Hutt and Cole (1954) maintained that the condition should not be included in the complex under discussion.

Experimental studies along this line are of special interest. Oberling and his associates (1938c, 1934) maintained birds in outdoor cages on a mineral-poor but otherwise adequate diet and observed lesions which showed a striking resemblance to human osteodystrophia fibrosa cystica associated with parathyroid hyperplasia. Gohs (1934a, b), on the other hand, produced a similar pathologic picture, save

for parathyroid hyperplasia, together with leukemic conditions, by repeated injections of normal embryonic or X-rayed adult avian bone marrow. Spontaneous cases pathologically resembling those of Gohs were described under the term osteopetrosis gallinarum (Jungherr and Landauer, 1938) and found to be transmissible. The agent could not be separated from that of lymphomatosis. While confirming the associated occurrence, Brandly et al. (1941) observed certain differences in occurrence, and Burmester (1947a), in sedimentability, between osteopetrosis and lymphomatosis which, according to them, suggest etiologic differences. Periosteal proliferation in long bones of chicken embryos receiving intravenous injections of normal blood or serum was observed by Brandly (1941) and his associates (1949). The condition described by Thiersch (1944) under the name of osteopathia hyperostotica scleroticans multiplex infantilis, following intravenous injection of embryos with human leukemia material, seems to be of similar nonspecific character.

Osteopetrosis differs from osteomyosclerosis, described in fowl by Seifried and Sassenhof (1940), as a disease sui generis, and is believed by Bloom et al. (1941) and Sjolte (1950) to represent a physiologic mechanism for calcium deposition during egg production.

Occurrence. In comparison with other manifestations of the avian leukosis complex, the occurrence of osteopetrosis is rare. Some field cases are sporadic in nature and often escape detection until the birds are dressed. This is borne out by observations of the United States poultry meat inspection service. Isolated epiornithic cases, predominantly in males, have been described. The geographic distribution appears to be widespread according to reports from Canada (Moynihan, 1943; Biely, 1943); Sweden (Magnusson, 1946); and South Africa (Coles and Bronkhorst, 1946). In a flock kept for experimental purposes, the latter authors observed 39 cases which were believed to show a famil-
FIG. 19.17—Osteopetrosis. The shanks of the birds are affected in various degrees. (Jungherr and Landauer, Storrs Agr. Exper. Sta.)

ial incidence and to be due to a unifactorial recessive character, in support of the contention of Hutt (1932), who found two of nine birds from the same dam to be affected with such abnormal osteogenesis.

Symptomatology. If the disease affects the metatarsi it can be detected on clinical inspection. Palpation of the long bones may reveal additional cases. In the beginning, diseased leg bones, to the exclusion of the phalanges, show abnormal convexities or irregular thickenings in the diaphyseal or metaphyseal regions. The affected areas are hot to the touch, hard, and insensitive. Advanced cases exhibit the characteristic "bootlike" thickening of the shanks (Fig. 19.17).

Pathology. The gross alterations of the skeleton may be observed in all the long bones of the extremities (Figs. 19.18 and 19.19), in the osseous components of the pelvis, shoulder girdle, and in rare instances also in the spine, while phalanges and skull bones seem refractory. X ray pictures examined by Edeiken (1940) were considered to show definite bone changes in the nature of osteosclerosis with thickening and increase in density of the cortex, encroachment and in some places obliteration of the medullary cavity (Fig. 19.19); the general features were regarded as similar to those of osteopetrosis in man.

The pathologic process affects primarily

the diaphysis, and is ordinarily bilateral. The intensity of the bone lesions varies widely from exostosislike cortical thickenings to massive asymmetrical involvement leading to almost complete obliteration of the marrow cavity. Even in the early stages the affected bones—though somewhat porous in appearance—give evidence of increased breaking strength. In cases of long standing they are extremely hard. Both cross (Fig. 19.20) and longitudinal sections of bones are helpful in the diagnosis.

The extent of the visceral changes is variable. Rapidly developing cases usually exhibit the gross characteristic changes of visceral lymphomatosis, while old arrested cases are more apt to show this association only on microscopic study of the tissues. The parathyroids appear normal.

The histopathologic picture of affected bones varies according to the maturation of the specific process. The initial phase is characterized by sequestration and granular degeneration of old trabeculae, marrow fibrosis, and increased osteoclasia. These changes, akin to those of osteodystrophia fibrosa, are accompanied by the development of a new large-celled vascular fibrous bone tissue which fails to show cartilage remnants or other evidence of endochondral ossification (Fig. 19.21). In the florid phase the new bone tissue gradually replaces both the original spongiosa and

compacta, while osteoclastic activity regresses. In the arrested phase, the new bone lamellae appear condensed, hypercalcified, and subdivided by numerous thick irregular cement lines (in formalin-fixed material) corresponding to the so-called "mosaic" structure of Paget's dis-

ease in man (osteitis deformans) (Fig. 19.22). All three phases may be observed in the same case or even the same bone section. Gross et al. (1959) observed an early increase in size and number of periosteal and endosteal cells which process they considered neoplastic, especially be-

FIG. 19.22 — Osteopetrosis. Section of meta-tarsus showing arrested lesions with "mosaic" structure. (Jungherr and Landauer, Storrs Agr. Exper. Sta.)

cause it was often accompanied by osteolysis (Swiss cheeselike). The later formation of imperfect lamellar bone they considered nonneoplastic. Campbell (1961) considered osteopetrosis as a virus-induced bone deformity caused by increase of osteoblastic activity. This may be associated with immaturity of gonads, atrophy of spleen, adenomas of kidney, tumors of liver, and hyperplasia of certain muscle groups (Campbell, 1963).

Hematology. The blood picture is ordinarily aleukemic. There is sometimes a relative or an absolute lymphocytosis. Evidence of secondary anemia is quite common and understandable in view of the progressive reduction of the hematopoietic tissue. The remaining bone marrow is intensively hyperplastic and on microscopic scrutiny shows basophil erythroblasts and erythrogonia, as in erythroblastosis. In spite of this hyperactivity of the marrow, the immature stages of erythropoiesis are not observed in the circulating blood.

Differential diagnosis. Among other avian osteopathies, rachitis and osteoporosis (rickets) can be differentiated from osteopetrosis by their epiphyseal formation of osteoid or porous bone tissue, accompanied in osteoporosis by parathyroid hyperplasia. Cases of osteopetrosis complicated by D-avitaminoses occur. In perosis (hock disease) there is twisting and flattening of the shanks, while the bone structure itself remains normal.

NEPHROBLASTOMA

Synonyms. Renal adenocarcinoma (Carr, 1956), embryonal nephroma, Wilm's tumor, nephroblastoma (Ishiguro et al., 1962; Walter et al., 1962).

The addition of this tumor as a patho-

FIG. 19.23 — Nephroblastoma in chicken. Dilated tubules with neoplastic epithelial lining. Sarcomatous degeneration of stromal connective tissue at margins. (Courtesy of Dr. T. N. Fredrickson, U.S. Regional Poultry Laboratory, East Lansing, Michigan.)

logic entity to the avian leukosis complex has been mentioned in the historical part. Although always considered rare, this tumor is now found routinely in birds subjected to condemnation on the processing line, according to G. S. McKee (Northeastern Avian Diseases Conference, 1963).

Gross focal tumors in the kidney may suggest such a diagnosis which must be verified histologically. The microscopic picture varies widely from simple hyperplastic tubules and attempts to form glomeruli (Fig. 19.23) to frank sarcomatous stroma. There may be islands of cartilaginous, osteoid tissue and epithelial pearls, all of which give the impression of a teratoid tumor. Metastases in field specimens are rare.

In uncomplicated cases the blood picture is normal. Histologic examination permits differential diagnosis from other conditions causing enlargement of the kidneys, such as visceral lymphomatosis and uric nephritis.

ERYTHROBLASTOSIS

Synonyms. Severe anemia, "light," intravascular lymphoid leukosis (Ellermann, 1921), oligoerythrocythaemia or erythromyelosis (Bayon, 1929, 1930), erythroleukosis (Ellermann, 1923 and Furth, 1931b), Leukomyelose (Kitt, 1931), the erythroblastic form of transmissible fowl leukosis (Olson, 1936), erythroblastosis (Engelbreth-Holm and Rothe-Meyer, 1932).

Following the initial report by Ellermann and Bang in 1908 and subsequent studies (1921, 1923) on the experimental production of fowl leukemia by parenteral transmission of blood or blood-forming tissues, only Schmeisser (1915) reported on the successful transmission of a spontaneous case. As doubts had thus arisen in regard to the transmissibility of fowl leukosis, Jármai (1930) and Furth (1931a) independently developed new transmissible strains of fowl leukosis which proved to be of the erythroblastic and erythrogranuloblastic type, respectively. These results were soon confirmed by Engelbreth-Holm

(1931) in Denmark, and Oberling et al. (1933) in France, and others. From the pathologic standpoint most investigators recognized an erythroblastic and a granuloblastic (myeloid) type. Since both of them occurred in subpassages either alone or together, irrespective of the disease in the donor, they were considered to be due to the same etiologic agent.

In transmission experiments on erythroleukosis, Ellermann (1923) observed severe cases of anemia and regarded them as hyperacute aleukemic expressions of the disease. Severe spontaneous anemia of fowl associated with lipochromatosis was considered to be different from Ellermann's erythroleukosis by Bedson and Knight (1924). By transmission of such cases, however, Stubbs and Furth (1932) were able to show their close relationship to erythroleukosis. Therefore, most investigators recognize that erythroblastosis may occur in a leukemic and an anemic subvariety (Olson, 1940).

Occurrence. In contrast to the amount of experimental work that has been conducted with it, erythroblastosis is of comparatively rare sporadic occurrence under field conditions. It is known to affect all standard breeds and occurs primarily after the age of six months (Olson, 1936). A notable exception is the report of Hamilton and Sawyer (1939), who observed the disease in five-week-old birds on an epiornithic scale.

Symptomatology. While birds in the early stages of erythroblastosis appear normal, within a short time the disease manifests itself by paleness or by a yellowish color of the unfeathered parts of the body, and by stupor and diarrhea; there is usually emaciation and loss of egg production. Uncontrollable bleeding from feather follicles has been observed at times. The anemic subvariety takes a chronic course over a period of several months.

Pathology. The carcass may be emaciated, at times obese. Although the tissues appear pale, there are often petechial hemorrhages in various places such as the mucosa of the small intestine, under the liver

capsule, or in the subcutaneous tissue. Terminally there is sometimes evidence of thrombosis, infarction, and rupture of internal organs. Edematous changes prevail in chronic cases. The most typical gross alteration is a diffuse enlargement of liver and kidneys and especially the spleen, associated with a cherry-red discoloration in fresh specimens. The parenchymatous organs are soft and friable. In uncomplicated cases there is no tendency toward the production of deforming tumors. Some of these changes may be absent, and even if they are well developed they are only suggestive and not diagnostic of the disease. Of special interest is the appearance, in normally lipo-pneumatic long bones, of the marrow which shows marked hemorrhagic hyperplasia and increased consistency described as "currant-jelly-like." The compacta of the long bones may undergo osteosclerotic changes (Bayon, 1930; Furth, 1931a).

In anemic cases of erythroblastosis the hyperplasia of the visceral organs and the bone marrow is absent; the spleen occasionally may be in a state of atrophy. The marrow spaces are often replaced to a large extent by a honeycombed spongy bone formation such as is seen in osteodystrophia fibrosa (Stubbs and Furth, 1932). Whether or not a given case of severe chronic anemia (asthenia in older textbooks) is causally related to erythroblastosis can be ascertained only by passage experiments.

On histologic examination, the lesions of erythroblastosis, aside from abnormal deposits of hemoglobin-derived pigments (Bayon, 1930), are characterized by dilatation of the blood sinusoids and capillaries which are filled to capacity with primitive blood cells of the erythroblastic series. This essentially intravascular process is called leukostasis (Furth, 1931b) and is particularly developed in the liver, spleen, and bone marrow. In studying the pathogenesis of the disease in the bone marrow, Pontén and Thorell (1957) found the sinusoids to show focal involvement within 3 days and diffuse involve-

ment within 7 days postinoculation. Nonspecific regeneration, following the use of hemolytic chemicals, commenced within 12 hours and was diffuse or "systemic" in character. Since mild hematologic changes suggestive of erythroblastosis may occur in other conditions, leukostasis is one of the prime features in the diagnosis of erythroblastosis.

In anemic erythroblastosis the visceral organs, especially the liver, often show extensive accumulations of small round cells and granulocytes which are probably reactive in character and difficult of interpretation. On careful search one is sometimes able to detect typical localized areas of leukostasis (Stubbs and Furth, 1932). According to Engelbreth-Holm (1932), the bone marrow quite regularly shows microscopic accumulations of erythrogonia which, however, fail to invade the blood stream.

Hematology. Even on gross examination the blood is often noticed to be pale, watery, and slow to clot. As shown by Furth (1931a), centrifugalized specimens of fresh normal blood show a plasma:leukocyte:erythrocyte ratio of about 55:1:44, erythroblastic blood of 88:1:11, and granuloblastic blood of 16:69:15. Centrifugation of fresh blood in chilled tubes may thus serve as a presumptive diagnostic test, and in the case of erythroblastosis also gives evidence of severe anemia. In properly stained smears the blood picture is characterized by the appearance of many basophile erythroblasts and erythrogonia, which are considered to be hemoglobin-free precursors of erythrocytes. Although these cells are not strictly leukocytes, they would show up as leukocytes by the ordinary leukocyte count technique. The number of immature erythrocytes in the circulating blood is relatively small, a few hundred thousand per cu. mm. (Furth, 1931b). The erythrogonia—which have been given the confusing name of lymphoidocytes by Ellermann—are highly characteristic; they vary in size, but are usually larger than the erythroblasts. In contrast to the "cartwheel-like" nucleus of

these cells, the nucleus of erythrogonia stains a peculiar violet-red (in Wright-Giemsa preparations), and appears either homogeneous or diffusely hromatic. Binucleated and mitotic figures occur among them. The cytoplasm appears narrow, basophilic, and occasionally vacuolated (colored illustrations, Furth, 1931b, and Oberling and Guérin, 1934). There is often an intense thrombocytopenia (Feldman and Olson, 1933), which may be due to a concomitant proliferation of the corresponding immature precursors, a thromboblastosis (Ishitani, 1957). The number of polychrome erythrocytes is comparatively small. This is in contrast to the situation in secondary anemias — which may occur spontaneously or be induced by repeated bleeding or by certain chemicals — in which polychrome erythrocytes together with anisocytosis and poikilocytosis dominate the blood picture (Furth, 1931b).

Differential diagnosis. The danger lies not so much in mistaking erythroblastosis for another disease as in not suspecting it if it is present in an atypical or chronic form. Confirmation of the diagnosis must rest upon hematologic and histologic studies.

MYELOBLASTOSIS

Synonyms. Leukemic myeloid or myelotic leukosis (Ellermann, 1922), Leukomyelose (Kitt, 1931), leucocythemia or leucomyelosis (Bayon, 1930), leukemic myeloblastosis (Nyfeldt, 1934), the granuloblastic form of transmissible fowl leukosis (Olson, 1936), granuloblastosis (Jungherr et al., 1941), myeloblastosis (Eckert et al., 1951), diffuse myeloid leukosis (Darcel, 1957).

As has been emphasized by Furth (1934), the description of leukemic and aleukemic types of myeloid leukosis by Ellermann (1920) comprised two pathologically different conditions, namely myeloblastomatosis, which is identical with myeloblastosis, and myelocytomatosis. Aside from this, the historical development of available knowledge on myeloblastosis and erythroblastosis has been much the same, due to tendency of these diseases to occur in a mixed form (Furth, 1931a). Nyfeldt (1934) claimed to have observed a pure strain producing only myeloblastosis. The development of a pure strain (BAI-A) of myeloblastosis (Beard, 1956), although later shown to have multiple cell responses, has been mentioned in the historical part.

Occurrence and symptomatology. There are no essential differences between myeloblastosis and erythroblastosis. Bayon (1930) believes that the former occurs mostly in old hens.

Pathology. In distinction from erythroblastosis, the disease has a tendency to bring about grayish mottling of the enlarged parenchymatous organs; the bone marrow appears "pale or pink and diffluent" (Bayon, 1930). The liver may have a granular or "morocco-leather" appearance (Chubb and Gordon, 1957). Otherwise, the anatomic changes are those described under erythroblastosis. Gross differential diagnosis between the two types is usually not possible (Olson, 1936). The histopathology of predominantly myeloblastic cases shows massive accumulation in the parenchymatous tissues of large myeloblastic and promyelocytic elements which are essentially extravascular, but overflow into the blood channels. There is therefore marked infiltration and substitution of the original tissues by the pathologic cells, in distinction from the fairly uniform intravascular leukostasis in erythroblastosis.

In the spleen the early changes seem to begin in the reticular stroma of the red pulp. The bone marrow shows intense myeloblastic activity in the extrasinusoidal areas, an observation which is particularly useful in pathogenetic studies. As may be surmised, the respective pathologic and hematologic features of erythro- and myeloblastosis show considerable overlapping in the mixed form.

Lagerlof and Sundelin (1963a) studied the histogenesis of the induced disease and found it to be similar to that of erythroblastosis (Pontén and Thorell, 1957) in that the bone marrow was attacked within
FIG. 19.24 — Comparison of blood smears from (above) myeloblastosis and (below) neural lymphomatosis. (Pappenheimer, Storrs Agr. Exper. Sta.)

3 to 4 days, but by the formation of multiple extrasinusoidal foci. Newly hatched chicks, inoculated with the virus in plasma samples, developed the "classic" form. Susceptibility decreased with age and some chicks developed subleukemic hemolytic anemia with lymphoid hyperplasia, splenomegaly, and splenic siderosis. Chicks inoculated at 14 to 21 days of age showed cases of visceral lymphomatosis, teratoid tumors, and hemangiomatosis (Lagerlöf and Sundelin, 1963b).

Hematology. The marked rise in the leukocyte column of centrifuged blood specimens has been mentioned (p. 419). The blood picture is characterized by the appearance of primitive cells of the myeloblastic series, especially myeloblasts (Fig. 19.21) and promyelocytes (colored illustrations, Oberling and Guérin, 1934) in large numbers, up to 2 million per cu. mm. (Beard, 1956), indicative of a leukemic or subleukemic state. The myeloblasts are large cells with slightly baso-

philic clear cytoplasm and a large vesicular acidophilic nucleus containing one to four nucleoli. Occasionally the leukemic elements are of the "Rieder" cell type (Olson, 1936). Promyelocytes and myelocytes have a similar nuclear structure, but can be definitely recognized by virtue of their specific granulation, which is primarily basophilic in the early forms, or grades into that of the three familiar types of adult granulocytes. The peroxidase test, useful in mammalian hematology for the recognition of the granuloblastic series, does not give equally sharp results with avian blood, according to Jover (1951). Hemocytoblasts are indistinguishable from myeloblasts; if they occur together with definitely granulated elements, the former term seems to be more confusing than clarifying. In addition to the blood alterations mentioned, there may be evidence of secondary anemia. Late myelocytes and metamyelocytes with the granulation of the mature heterophil are rare.

MYELOCYTOMATOSIS

Synonyms. Aleukemic myeloid leukosis (Ellermann, 1920), leukochloroma (Mathews, 1929), myelocytoma (Pentimalli, 1915; Feldman, 1932), myelocytomatosis (Furth, 1933), aleukemic myeloblastosis (Nyfeldt, 1934), myeloma, discrete myeloid leukosis (Darcel, 1957).

While it is difficult to state the exact nature of the disease described by Ellermann as aleukemic myelosis, Pentimalli (1915) first recognized the distinctive character of the tumor found in this disease, which Mathews (1929) described as an essentially aleukemic neoplasia. In passage experiments of lymphomatosis (strain 2) Furth (1933) observed leukemic cases of myelocytomatosis and considered both to be pathologic expressions of the same agent. "Pure" transmissible strains, with the possible exception of Nyfeldt's strain (1934), have apparently not been described in the literature. According to the available experimental evidence, myelocytomatosis is thus related to lymphomatosis, while everyday pathologic experience tends to place it closer to the ordinary tumors.

Occurrence and symptomatology. Sporadic cases are apt to occur in young adult birds, some of which are seen in flocks that do not show any other pathologic evidence of the avian leukosis complex. The clinical appearance is noncontributory to the diagnosis.

Pathology. Myelocytomatosis characteristically forms tumors which figure among the few avian representatives which can be recognized on gross examination with some degree of certainty. The new growths are a yellowish-white color, resemble congealed cream in appearance and consistency, and are often of multiple anatomic origin. The masses may be found in the muscle tissue and visceral organs, and especially along the ribs or other parts of the skeleton bordering the body cavities, and may exert pressure on the spinal cord.

Histologically, the tumors consist of compact masses of myelocytes which are strikingly uniform in appearance and have the typical full acidophile granulation of either the mature eosinophil or the heterophil. The stroma is very scanty. In certain parenchymatous organs, such as the kidneys, the tumors show infiltrative growth. The bone marrow, as a rule, exhibits myelocytic hyperplasia. The type cell is ordinarily round, but may appear fusiform in areas subject to pressure.

Hematology. Uncomplicated cases are usually aleukemic, although there may be a heterophile leukocytosis. If definite leukemic blood involvement occurs, the hematologic picture is dominated by the appearance of polychrome myelocytes and acidophilic metamyelocytes.

ETIOLOGY

Discussion of the etiologic aspects of the avian leukosis complex presents difficulties which are brought about by the lack of definite information on the causal relationship of the various forms of tumor and the relationship of the known agents to tumor induction. As is expected with a disease of almost universal occurrence and obscure etiology, the literature contains a wide variety of suggested causes. Some points are of more or less general applicability.

Most observers are in agreement with the opinion of the early investigators (Marek, 1907; Pappenheimer et al., 1926; Ellermann and Bang, 1908) that the condition is not caused by a cultivable organism of bacterial or fungal nature. Gray (1938) sometimes isolated Coccaceae from affected nerves.

On the evidence that field cases of fowl paralysis and allied conditions occur frequently in association with coccidiosis or helminthiasis, some students believe that parasitic conditions act as predisposing, precipitating, or even causal factors. Bayon (1930), for instance, observed Davainea proglottina infection in erythroblastosis and severe anemia, and considered it to be a contributory factor, while Stubbs and Furth (1932), studying the same disease, failed to observe this association. The fact that typical cases of the various diseases

of this group have been produced under controlled laboratory conditions (Warrack and Dalling, 1932) militates against a synergistic concept in the causation of the avian leukosis complex. Caranti (1956) believed cases which pathologically correspond to neural lymphomatosis to be causally related to coccidiosis. The diagnosticians observing field cases continue to suggest some relationship between coccidia and leukosis, however, the question of predisposing and aggravating factors must remain open and should best be attacked on an experimental rather than a statistical basis.

Some nutritional aspects were studied by Wilcke and his associates (1933), who found no significant differences in the incidence of fowl paralysis when the rations varied in mineral and vitamin levels. Blount (1932) interpreted this disease in terms of a B-hypervitaminosis or, more generally, of a gastronomic enteritis. On the basis of observing functional curative effects from the feeding of lettuce (Bayon, 1932), or a decrease in the incidence of the leukotic diseases following the feeding of additional wheat germ oil (Butler and Warren, 1958; together with Hammersland, 1958), some authors suggested the possibility of an underlying E-hypovitaminosis; the latter contention could not be supported by critical experimentation (Jungherr, 1910; Taylor and DeOme, 1939). Adamstone (1936), however, claimed to have produced a "lymphoblastoma"-like condition in chicks reared on a diet which had been treated with ferric chloride for the purpose of destroying vitamin E.

Biely and March (1959) studied the effect of nutrition on the level of leukosis mortality in 4 strains of chickens, 2 of which were considered susceptible. In all 4 of the strains, the incidence of tumors was lowest in those chickens raised and maintained on a low plane of nutrition as compared with the same birds on a high plane of nutrition. Olson et al. (1962) found one particular lot of cod liver oil to increase the incidence of lymphomatosis induced by exposure to low doses of viral inoculum or contact. The incidence of erythroblastosis induced with the same material in high doses was not altered.

Nonspecific factors such as Salmonella toxins, vitamins A and K and iron deficiencies, poor ventilation, etc., have been claimed by Emmel (1939) to be the basic process in the development of the avian leukosis complex. McIntosh and Selbie (1939) believed they produced filterable tumors in fowls by the injection of tar, but extended studies by Murphy and Sturm (1941a, b) and more recently by Crispins (1960) on chemically induced tumors have failed to establish transmissibility of cell-free materials. Such transmission continues to be described but not under circumstances where concurrent or subsequent virus contamination could be ruled out.

The heritability of resistance and susceptibility to death from tumors has been studied in the laboratory and through field observations.

Bayon (1932) voiced the widespread opinion that the incidence of fowl paralysis was higher in the progeny from certain strains of fowls. Asmundson and Biely (1932) and Biely et al. (1952) found differences in the resistance to fowl paralysis, which they interpreted as due to a dominant inherited factor. Hutt (1939) and his associate (1918) observed reduction from 15 to 5 per cent in adult mortality due to neoplastic diseases after twelve years of selecting disease-resistant lines. Cole (1911) developed White Leghorn resistant and susceptible lines for an artificially transmissible sarcoma (Jungherr, 1937), but found they showed no differences in spontaneous mortality which was principally due to lymphomatosis. Purchase (1963) reported preliminary results indicating that RPL line 7, resistant to infection with RPL-12 and Rous virus, is very susceptible to JM virus. This would indicate that genetic resistance to one type of neoplasia does not necessarily mean resistance to neoplastic disease in general. In ordinary observations it is difficult to differentiate between genetic susceptibility and actual transmis-

sion via the egg of the causative agent, maternal antibodies, or both. Systematic studies have been undertaken to elucidate the genetic factors which govern resistance and susceptibility to lymphomatosis. By progeny-test selection over a period of eight years, Taylor et al. (1915) observed significant differences in the incidence of the disease between resistant and susceptible lines, but could not attribute them to sex-linked genes or to predominantly egg-borne transmission. The method of selection was believed to create a useful degree of relative resistance to lymphomatosis. On the basis of five years of selective breeding under conditions of rigid quarantine, Waters (1915b) demonstrated definite segregation of genes for resistance and susceptibility to lymphomatosis and emphasized the progressive nature of the process in contrast to previous workers who rarely achieved reduction of the disease below the initial percentage incidence. Differences between two sires became apparent when both were mated to the same dam (Waters, 1915c).

Burmester et al. (1960c), in reporting on many years' study with the highly inbred strains of chickens and RPL-12 and Rous sarcoma virus, stated that the several lines responded very differently to exposure to the viruses and that certain of the inbred lines responded differently to the two viruses. Waters and Burmester (1961) presented evidence that in the inbred RPL chickens, susceptibility to intracerebral inoculation with Rous sarcoma virus is dominant to resistance and is dependent for expression on a single pair of autosomal genes.

Work with open-bred stocks does not suggest a simple genetic relationship between tumor resistance and susceptibility. In testing the resistance and susceptibility by artificial exposure, DeOme (1943) found intraperitoneal injections of lymphomatous nerve tissue to cause a more or less parallel increase of the incidence in both the high and low lines. Hendorf et al. (1917), failed to differentiate between resistant and susceptible lines using intraperitoneal injec-

tion of tumorous materials, but obtained significant differences by exposure in the mouth, eyes, or nostrils. This technique failed to increase the incidence of clinical signs in commercial breeding birds sufficiently to make selection more effective.

On the other hand, Carson (1951) exposed chickens from known resistant and susceptible lines to avian leukoses to various viral, bacterial, and protozoal agents without observing a consistent correlation between the genetic constitution for neoplastic and infectious diseases. On the basis of nine years' data, Waters (1951) reported an over-all increase of mortality from lymphomatosis in lines especially selected for susceptibility to this disease, but did not consider such susceptibility or resistance a fixed genetic character. Mortality from other causes failed to show a corresponding increase by his analysis, contrary to the results of Oakberg and Lucas (1919a, b, 1950) on essentially the same material.

Dr. F. B. Hutt established a long-term leukosis project in 1935 which included the development of resistant and susceptible lines. In papers published in 1954 and 1955, Hutt and Cole pointed out the difficulties of providing a standard exposure year after year, particularly of maintaining susceptible populations, and suggested exposing only portions of families in order to have samples of the most susceptible families available for breeding purposes.

In a summary of their work presented by Cole (1962) at the Avian Leukosis Conference, it was reported that for unknown reasons, the level of mortality had decreased in the susceptible strains. Their results over the years have been consistent with the hypothesis that resistance in the strains depends upon many genes. In 1954, samples of line 15 susceptible chicks from East Lansing Laboratory were hatched and raised with the Cornell resistant and susceptible lines. Mortality in the Cornell susceptible lines was approximately 50 per cent whereas mortality in the RPL susceptible line 15 and Cornell resistant strains was on the order of 1 to 4 per cent.

This is most easily interpretable on the basis that the diseases under study at the two laboratories are different.

To attain resistance in the average breeding flock was considered by Coles (1954) to be a 5- to 6-year program. Waters (1954) concluded that hybridization of inbred lines of chickens with various degrees of resistance failed to decrease the mortality from lymphomatosis. The mode of inheritance of resistance to either neural or visceral lymphomatosis could not be elicited.

Bearse et al. (1963), working with lines selected for susceptibility and resistance for 28 generations, reported that when crosses and back crosses were made between resistant and susceptible lines, the leukosis mortality results of the F-1 crosses were between those of the resistant and susceptible lines, whereas mortality from causes other than leukosis was lower than the corresponding mortality in the resistance lines indicating that heterosis was not affecting leukosis mortality but did lower other mortality.

Breeders of commercial chickens believe they have attained a status in which the incidence of tumors in commercial breeding populations is too low for effective selection for resistance. The application of various techniques to increase incidence has either failed to increase the number of tumor cases or has not differentiated between susceptible and resistant families. Unless new means of measuring resistance in breeders can be found, genetic selection cannot be expected to eliminate the problem of leukosis losses.

That sex hormone balance may influence the incidence of lymphomatosis and perhaps activate a latent agent, was suggested by Marine and Rosen (1941). Oakley (1935) already was impressed by the higher incidence of the visceral form in females than in males, while for the osteopetrotic form the reverse seemed to be true (Pugh, 1927; Brandly et al., 1941). Burmester (1945) observed the incidence of natural lymphomatosis to be twice as high in females as in corresponding males during the first 300 days. In further studies along this line, Burmester and Nelson (1945) tested the influence of castration and of sex hormones and credited the male hormone with conferring increased resistance to lymphomatosis, while Davis et al. (1950) believed such altered susceptibility to be a matter of nonspecific hormonal imbalance.

A transmissible agent of fowl leukosis capable of passing through bacteria-retaining filters was first demonstrated by Ellermann and Bang (1908), and subsequently confirmed by many investigators (Jármai, 1930; Furth, 1931a, 1936b; Thomsen and Engelbreth-Holm, 1932; Oberling and Guérin, 1934). A similar etiologic agent was postulated for neurolymphomatosis by Van der Walle and Winkler-Junius (1924), Pappenheimer et al. (1926), Johnson (1932), and others, and for lymphomatosis by Furth (1933). These agents are similar to that of the Rous (Claude and Murphy, 1933; Foulds, 1934) sarcoma in being ultramicroscopic in nature and capable of producing a variety of neoplastic diseases in the fowl (Furth, 1932a), but differ in their inability to cause tumors at the site of injection (Burmester, 1950). They have been termed microplasms, transmissible agents, enzymes (Jármai, 1935), or oncogenic viruses. Oberling and Guérin (1954) could see no valid reason to set such agents apart from ordinary viruses.

The recent advances in the characterization of the avian leukosis viruses which have been sufficiently studied, and the available methodology, have been summarized by Beard (1957a, b).

According to him, the virus of erythroblastosis, if injected intravenously into inbred susceptible chicks, produces recognizable hematologic changes within 2 days and death on the average within 9 days. It lacks the enzymatic capacity to dephosphorylate adenosine triphosphate, and has no Forssman antigen. It is only slightly precipitable by homologous antiserum; whether this is due to the usual, relatively

low concentration of virus particles awaits further study.

By contrast the *virus of myeloblastosis* produces recognizable hematologic changes within 9 days and death on the average in 17 days. It has pronounced capacity to dephosphorylate adenosine triphosphate and a strong Forssman antigen. It is readily precipitable by homologous antiserum, and is usually present in high concentration.

According to Eckert *et al.* (1963) the myeloblastosis virus resembles in size and chemical composition the myxoviruses. The shape of the virus particle is generally believed to be spheroid, but there is a certain percentage of phagelike tailed particles, according to Bartl *et al.* (1963).

The characterization of the *virus of lymphomatosis* is less complete. Burmester and Gentry (1956) observed that RPL-12 filtrates, originally obtained from the Olson (1941) tumor caused "intravascular" lymphomatosis (morphologically indistinguishable from erythroblastosis), with an incubation period of less than 4 months, if given in high doses; and "extravascular" lymphomatosis, with an incubation period up to 9 months, if given in low doses. Both pathologic conditions were accompanied by the occasional occurrence of osteopetrosis, and rare fibrosarcomas and endotheliomas (Burmester, (1957a). In further studies (1957b) the properties of RPL-12 proved to be similar to those of lymphomatosis agents obtained from embryonated eggs, incubator debris, and oral, tracheal, and fecal washings. The RPL-12 filtrates could be neutralized not only by homologous antiserum, but also by that of known erythro- and myeloblastosis, Rous sarcoma, and spontaneous visceral lymphomatosis cases. The question of the etiologic unity of the three main pathologic entities, namely erythroblastosis, myeloblastosis, and osteopetrosis, was left undecided. The positive adenosine triphosphate activity of spontaneous lymphomatosis, reported by Lesher and Burmester (1955), would be at variance with that of known erythro-

blastosis (Bonar *et al.*, 1957). Furthermore, on the basis of cytologic studies, Darcel and Negroni (quoted by Chubb and Gordon, 1957) are inclined to view the conditions produced by RPL-12 as aleukemic variants of erythroblastosis.

In more recent work, Burmester *et al.* (1959b) reported that erythroblastosis and myeloblastosis viruses administered in doses allowing survival of the immediate effects of these diseases produced lymphomatosis and other tumors including osteopetrosis and renal tumors. This paper has not resolved the question of the relationship between tumor viruses, since mixtures of viruses could have occurred.

In a series of papers, the East Lansing workers (Gross *et al.*, 1959; Burmester *et al.*, 1959a, 1960a) describe the pathogenicity of RPL-12 virus and its relationship to the host. The lesions produced are erythroblastosis, visceral lymphomatosis, osteopetrosis, and hemangiomatosis. The level of infective virus applied had a marked effect on the type of neoplasm which developed, with erythroblastosis predominating at high levels of virus and lymphomatosis at low levels. In relationship to the age of the host, sensitivity to intravenous inoculations started decreasing when chicks were about 3 weeks of age and continued to decrease to about 12 weeks. By the oral route, sensitivity decreased very sharply during the first 3 weeks and decreased more slowly beyond that age.

The use of Rous sarcoma virus in tumor investigations has been increasing. Burmester *et al.* (1960b) reported the first recorded transmission of Rous sarcoma under conditions of direct bird-to-bird contact which resulted in the development of Rous sarcomas in the contact birds. In further work, Burmester and Walter (1961) reported the occurrence of visceral lymphomatosis in chickens inoculated with dilute preparations of Rous sarcoma virus which survived to the age at which visceral leukosis occurs.

The complicated serologic interrelationships — based on virus neutralization tests

in vivo — of the three recognized avian leukoses and Fujinami sarcomas, to Rous sarcoma, were summarized and diagrammed by Beard (1957a). The relationships varied from complete mirror neutralization between myeloblastosis and Rous sarcoma to partial or unilateral reactions. Each virus was shown to have a species-specific and a host-specific antigenic component. Beard (1957a) believed the three leukosis agents to constitute biologic entities of a large, closely related family of viruses which may also be responsible for virus-induced avian sarcomas. He speculated that these entities could be mutants of a stem virus, with contagious lymphomatosis providing the mode for perpetuation in nature.

From the beginning, leukosis investigations have been handicapped by a lack of suitable means for detection of the causative agents. Kissling (1947) described a slide leukoagglutination test with formalinized lymphocytes from chickens or various mammals (except oxen) for the diagnosis of avian lymphomatosis and believed the test to be primarily tissue- and not tumor-specific. Darcel (1950) found good correlation of this test with severely affected birds, only slight correlation with clinically "normal" birds, but inconsistencies in consecutive examinations. The potentialities of the phosphatase activity test (Lesher and Burmester, 1955; Anonymous, 1955) have not been explored sufficiently for practical purposes. A report of the United States Bureau of Animal Industry Regional Poultry Research Laboratory (1951) concluded that the only known method for demonstrating the lymphomatosis agent was the inoculation of susceptible chickens.

Kenzy (1953) described the technique for detecting antibodies to Rous sarcoma. The technique utilized *in vitro* incubation of unknown sera with known quantities of Rous virus and subsequent inoculation into chicks. The test was interpreted on the basis of the number and virulence of tumors developing in the inoculated

chicks. A subsequent paper (Kenzy and Neuzil, 1953) reported high percentages of sera containing Rous neutralizing antibodies from flocks with high losses from leukosis and lower levels of Rous neutralizing antibodies in birds which were grossly and microscopically normal.

Rubin, who had developed a tissue culture assay technique for Rous sarcoma virus, reported (1960) the presence of a virus in chicken embryos which induced resistance in tissue culture to superinfection with Rous sarcoma virus. The virus was shown to be associated with leukosis and related antigenically to RPL-12. The technique was developed into a test for the virus and it was shown that antibody to the resistance-inducing factor (RIF) was very closely related to Rous virus antigenically so that direct Rous neutralization tests were an excellent measure of the leukosis virus antibody. Epidemiologic studies (Rubin et al., 1961) using these tests showed that congenital transmission of the virus was very frequent in the population under study, that passive immunity was effective in delaying contact infection until chicks were about 6 weeks of age, and that spread of the virus continued until all birds in contact were infected.

Rubin has continued his studies with Rous sarcoma virus. Of possible significance in the study of leukosis is his detection of a second virus in standard stocks of Rous sarcoma (Rubin and Vogt, 1962) and the later demonstration by Hanafusa et al. (1963) that Rous sarcoma is defective and requires a helper virus, presumably one of the resistance-inducing group, to complete its biologic cycle.

Sevoian et al. in a series of papers (1962, 1963a, and 1963b) described an agent causing neural and visceral lymphomatosis. This virus, labeled JM, produces lesions in a relatively short time after infection, 2 to 5 weeks, in the nerves and particularly the gonads as well as other visceral organs. Neural lesions tend to predominate in young birds and visceral lesions in older birds, duplicating in part field cases of

lymphomatosis. The agent was shown to be transmitted via the air-borne route. The only test for the virus currently available is the inoculation of susceptible chicks.

Present evidence suggests that JM virus and the resistance-inducing leukosis viruses are unrelated. Calnek (1963) has stated that he believes the JM virus does not induce resistance to Rous virus. Burmester has provided evidence that RPL-12 is not spread by the air-borne route and observation resulting from Rubin's studies would support this observation, whereas the JM virus has been demonstrated to be infectious by the air-borne route. Confirmatory evidence must await new means of assay of the JM virus.

Most European investigators have separated the leukosis complex into lymphoid, myeloid and erythroleukosis, and Marek's disease. Campbell (1961) has proposed a classification system for these diseases. Biggs (1961) concluded that the cells from Marek's disease could not be differentiated histologically from those of lymphoid leukosis on histopathologic grounds alone. He reported that there may be a difference in the competence of cells in cell suspensions, with those from Marek's disease retaining their competence and those from RPL-12 lymphoid tumors showing no competence in the graft against host reaction in chicken embryos.

The status of information about Marek's disease does not allow any determination as to its relation with JM virus, though it seems likely that it can be differentiated from the RPL-12 type viruses.

The Rous resistance-inducing test provides the first useful *in vitro* test for the detection of a leukosis virus and its antibody. Of foremost interest are tests to detect viruses of the Marek and JM types and a simpler test for resistance-inducing viruses.

TRANSMISSION

The investigations of Burmester and the Regional Poultry Laboratory staff and of Rubin *et al.* (1961) have very definitely es-

tablished the mode of transmission of the resistance-inducing leukosis viruses. The literature, as indicated in the following discussion, points up the serious difficulty investigators through the years have encountered in studying leukosis. One of the most confusing problems in determining the method of transmission of infection has been that the gross manifestation of disease (the tumor) is not an invariable consequence of infection with the virus.

The earlier contentions of Doyle (1928) and McGaughey and Downie (1930) on the transmission of fowl paralysis through the egg did not find support in direct embryo inoculation experiments with this disease by McLennan (1935) or with erythroleukosis by Jármai (1933). Gibbs and Johnson (1955) claimed to have observed the characteristic pathologic cells of neurolymphomatosis in the follicular or seminal fluid of affected birds, while Storti and Mezzadra (1938) observed survival but not multiplication of the leukosis virus in 4-day-old chicken embryos. Van den Berghe and d'Ursel (1939) apparently transmitted the leukosis agent to chicken embryos, and Pollard and Hall (1941) to embryos of other avian species. Extensive breeding experiments by Lee and Wilcke (1941) indicated that the incidence of the leukosis complex is much higher in the progeny from iritis-affected birds than from normal birds, especially if either the female or both parents were affected. Carrying on a similar breeding experiment, Durant and McDougle (1939) and Lee and Wilcke (1941) were able to demonstrate the agent of fowl paralysis in the blood of recently hatched normal chicks. A well-planned, practical transmission experiment with neural lymphomatosis by Gordon *et al.* (1955) suggested spread by contact, but the possibility of transmission via the egg could not be ruled out.

Waters (1945a) pointed out the importance of the egg as a carrier, since simple importation of hatching eggs into an entirely new isolated poultry plant resulted in the spontaneous appearance of

lymphomatosis in chickens within 40 days after hatching. Later, Cottral et al. (1949) actually accomplished the transmission of visceral lymphomatosis with tissues from 15- and 18-day-old embryos and newly hatched chicks, derived from parents free from gross evidence of the disease up to the age of 600 days.

On the basis of these inductive experiments, avian lymphomatosis was ranged among the egg-borne carrier diseases by Cottral (1949).

In contrast to this view, Hutt and Cole (1947) questioned the importance of egg transmission of lymphomatosis, especially in comparison with genetic and environmental factors, and also referred to the work of Carr (1945), who failed to observe egg transmission in Rous sarcoma. Cole (1949) summarized the evidence pro and con for egg transmission and minimized its importance. Analyzing the results with resistant and susceptible birds kept under controlled environmental conditions, Cole and Hutt (1951) presented evidence that leukosis is not transmitted through the eggs. The discrepancy may be explained, in part, by the fact that Cole and Hutt were dealing primarily with neural lymphomatosis for which egg transmission has not been demonstrated.

On the basis of field observations, pathologists with large commercial breeders of egg-laying chickens who have recorded major leukosis losses, agree that there is no direct relationship between egg or hatchery transmission of virus and severe leukosis losses in commercial poultry flocks. This conclusion has been reached on the basis of observations of large numbers of shipments of chicks over a period of many years.

The question of transmission of lymphomatosis by contact has been subjected anew to experimental inquiry. Barber (1942, 1913) reported a lower incidence of leukotic diseases in comparable groups of birds reared away from, than on, known infected premises. In analyzing neoplastic mortality in sexually mature birds over a period of seven years, Hutt et al. (1944)

observed a decreased incidence, independent from genetic background, in lots of birds that had been brooded for the first two weeks about 200 feet (in comparison with 40 feet for the controls) away from old birds. Environmental factors other than proximity to infected adults, such as restriction of food intake, crowding, and rapid growth-inducing rations, increased the mortality during the first six weeks, but failed to enhance the incidence of leukotic diseases during the succeeding 65 weeks (Cole and Hutt, 1949). Studies on the influence of the environment culminated in the development, by a system of selective breeding and extremely rigid sanitation, of a strain of birds essentially free from lymphomatosis by Waters and Prickett (1944). The unique contagious nature of lymphomatosis in chickens, in contrast to most mammalian and avian tumors, was brought out by Waters (1947). Support for this thesis has come from the work of Brewer and Brownstein (1947) in this country and Harriss et al. (1947) in England.

Waters and Bywaters (1919) made the observation that contact transmission, probably via the respiratory tract, may already take place in the incubator. Continuing this line of thought, the workers at the Regional Laboratory were able to show the presence of the lymphomatosis virus in incubator debris and in most of the secretions and excretions. In this connection, two new observations contributed materially to the present-day concept of spread of lymphomatosis: the shedding of the virus not only by affected chickens but also by apparently normal chickens (Burmester, 1956); and the demonstration of passive antibodies in chicks from hyperimmunized dams (Burmester et al., 1957). Although such antibodies may be protective, they are not sufficiently strong to neutralize the virus which may coexist in their presence.

The recent epidemiologic studies of Rubin et al. (1962) with the resistance-inducing test have confirmed and extended these observations. Using this test Hughes

lymphomatosis. The agent was shown to be transmitted via the air-borne route. The only test for the virus currently available is the inoculation of susceptible chicks.

Present evidence suggests that JM virus and the resistance-inducing leukosis viruses are unrelated. Calnek (1963) has stated that he believes the JM virus does not induce resistance to Rous virus. Burmester has provided evidence that RPL-12 is not spread by the air-borne route and observation resulting from Rubin's studies would support this observation, whereas the JM virus has been demonstrated to be infectious by the air-borne route. Confirmatory evidence must await new means of assay of the JM virus.

Most European investigators have separated the leukosis complex into lymphoid, myeloid and erythroleukosis, and Marek's disease. Campbell (1961) has proposed a classification system for these diseases. Biggs (1961) concluded that the cells from Marek's disease could not be differentiated histologically from those of lymphoid leukosis on histopathologic grounds alone. He reported that there may be a difference in the competence of cells in cell suspensions, with those from Marek's disease retaining their competence and those from RPL-12 lymphoid tumors showing no competence in the graft against host reaction in chicken embryos

The status of information about Marek's disease does not allow any determination as to its relation with JM virus, though it seems likely that it can be differentiated from the RPL-12 type viruses.

The Rous resistance-inducing test provides the first useful *in vitro* test for the detection of a leukosis virus and its antibody. Of foremost interest are tests to detect viruses of the Marek and JM types and a simpler test for resistance-inducing viruses.

TRANSMISSION

The investigations of Burmester and the Regional Poultry Laboratory staff and of Rubin *et al.* (1961) have very definitely established the mode of transmission of the resistance-inducing leukosis viruses. The literature, as indicated in the following discussion, points up the serious difficulty investigators through the years have encountered in studying leukosis. One of the most confusing problems in determining the method of transmission of infection has been that the gross manifestation of disease (the tumor) is not an invariable consequence of infection with the virus.

The earlier contentions of Doyle (1928) and McGaughey and Downie (1930) on the transmission of fowl paralysis through the egg did not find support in direct embryo inoculation experiments with this disease by McLennan (1935) or with erythroleukosis by Jármai (1933). Gibbs and Johnson (1955) claimed to have observed the characteristic pathologic cells of neurolymphomatosis in the follicular or seminal fluid of affected birds, while Storti and Mezzadra (1938) observed survival but not multiplication of the leukosis virus in 4-day-old chicken embryos. Van den Berghe and d'Ursel (1939) apparently transmitted the leukosis agent to chicken embryos, and Pollard and Hall (1941) to embryos of other avian species. Extensive breeding experiments by Lee and Wilcke (1941) indicated that the incidence of the leukosis complex is much higher in the progeny from iritis-affected birds than from normal birds, especially if either the female or both parents were affected. Carrying on a similar breeding experiment, Durant and McDougle (1939) and Lee and Wilcke (1941) were able to demonstrate the agent of fowl paralysis in the blood of recently hatched normal chicks. A well-planned, practical transmission experiment with neural lymphomatosis by Gordon *et al.* (1955) suggested spread by contact, but the possibility of transmission via the egg could not be ruled out.

Waters (1945a) pointed out the importance of the egg as a carrier, since simple importation of hatching eggs into an entirely new isolated poultry plant resulted in the spontaneous appearance of

be remembered that temporary remissions of the clinical signs may occur spontaneously.

With the new recognition of the role of the bursa of Fabricius in leukemogenesis, reduction of its influence on the incidence of lymphomatosis has been approached experimentally in two ways: dipping of eggs in testosterone propionate by Glick (1963), and bursectomy before the age of one month by Peterson et al. (1963).

In vaccination attempts for the prevention of the avian leukosis complex, Fritzsche (1938) failed to immunize birds against fowl paralysis with formol-treated tissue vaccine. Uhl (1938) secured some degree of immunity against erythrogranuloblastosis with aluminum hydroxide-adsorbed tissues. Johnson (1945) tried out several types of vaccines with inconclusive results. The demonstrated oncolytic action of certain neurotropic viruses on avian lymphoid tumors is of interest (Sharpless et al., 1950). The first tangible results were obtained by Burmester et al. (1957) who found that various types of vaccines, except heat-killed ones, repeatedly administered to chickens under one year of age, conferred a substantial immunity to their progeny. This work was of major consequence because it established the fact that the well-known principle of passive immunity held for visceral lymphomatosis. A concomitant reduction in the incidence of osteopetrosis was of taxonomic interest. At present the practical expectations from this work should be tempered.

Although an absolute control program for the avian leukosis complex cannot be suggested, there are two major avenues of approach, namely by breeding for resistance and by sanitation. In view of the pathologic and apparent etiologic diversity of the disease group, the effectiveness of a control program will vary with the prevalence of the respective forms. Thus, of the most common ones, neural lymphomatosis seems to respond more to selection, visceral lymphomatosis to sanitation. That there are puzzling failures is indicated by the reported increased incidence of visceral lymphomatosis even in broiler flocks (Benton and Cover, 1957; Benton et al., 1962), and turkeys (Simpson et al., 1957).

While the interaction of heredity and infectious agents in the environment, starting with the formation of the egg, is not fully understood, a disease complex estimated to cause losses in the United States of $1,000,000 per week (Hutt, 1944) calls for the intelligent application of all available facts.

In general, birds showing clinical evidence of the avian leukosis complex, including true ocular lymphomatosis, should be consistently culled. Frequent laboratory checkups on the causes of mortality are advisable.

1. By systematic selection of the progeny for resistance to lymphomatosis, it is possible to obtain relatively resistant strains of birds (Taylor et al., 1943). In this it is preferable to choose breeders whose brothers and sisters have shown the lowest incidence of the avian leukosis complex (Gildow et al., 1940). Insofar as is known, the progeny of resistant stock remains fully susceptible (Blakemore, 1959). A selective breeding program for general livability also tends to decrease the incidence of avian leukotic diseases, according to Bryant and Johnson (1944). Under practical conditions, breeding from the survivors of natural selection and especially maintenance of a "closed flock" with a minimum of importations have given the most tangible results.

Although ordinary sanitary methods are generally conceded to be insufficient to prevent entirely the occurrence of avian lymphomatosis (Waters, 1945a; Harriss et al., 1947), hygiene as a factor in the control of the avian leukosis complex has been shown to be of major importance. On the thesis that control of the avian leukosis complex should be achieved by rearing genetically resistant stock in the best possible environment, Hutt (1951) and Hutt and Cole (1954) have clearly set forth a program which combines the genetic and sanitary features and is adaptable to various managerial situations.

et al. (1963), succeeded in producing an experimental flock of chickens free of the resistance-inducing viruses. Levine and Nelsen (1964) followed a similar approach but found a significant portion of the breeding hens (25 per cent) to lack antibodies to Rous virus and RIF agents in their progeny, perhaps indicating no infection in a known infected environment. It seems that individual criteria have to be established in attempts to develop RIF-free flocks. Furthermore the demonstration of occasional genetic resistance of chicken embryos to Rous virus by Crittenden et al. (1963) and the report of antigenic plurality of Rous virus by Simons and Dougherty (1963) and its confirmation by Bang and Foard (1963) may complicate the interpretation of the RIF test.

The available information on the natural and artificial transmission of avian lymphomatosis has been reviewed by Burmester (1957a) and Gross (1957). Visceral lymphomatosis was considered to be the only known contagious avian tumor. The resistance-inducing viruses may be shed in nearly all eggs laid by tolerant hens and in occasional eggs laid by hens with circulating antibody (Rubin et al., 1962). This virus spreads to pen mates by intimate contact. Available evidence suggests that spread is very limited by indirect means.

The JM virus described by Sevoian and Chamberlain (1963) appears to be an unrelated virus. Early evidence suggests that it is spread via the air-borne route as well as by contact. Although no definite study has yet been reported, if the JM virus is related to the condition observed by Hutt and Cole over many years or to the agent causing neural losses in the field, egg transmission is not likely to be an important factor in the development of such tumors.

The presence of the avian leukoses agents in the blood stimulated research on blood sucking parasites as intermediaries. While most of the experiments were negative (Olson, 1940), Johnson (1937) showed the common red mite, Dermanys-

sus gallinae, and Brown and Cross (1941) the Texas "blue bug", Argas persicus, to be possible mechanical vectors of the lymphomatosis agent. Although not supported by experimental evidence, Carr (1952) re-emphasized the importance of blood-sucking parasites in the transmission of the diseases of the avian leukosis complex. This opinion was recently supported by successful laboratory transmission of Rous sarcoma virus by Aedes aegypti and A. albopictus (McDaniel et al., 1962). In further studies the same authors (1964) found the virus to survive and perhaps multiply in Culex pipiens pipiens, which commonly attacks birds, for at least 16 days. Johnson (1937) also suggested that minor operations, as in fowl pox vaccination, may have the same effect.

On the belief that the egg may be invaded by the lymphomatosis agent both at the time of formation and after commencing its independent existence, Cottral (1949) pointed to the danger of incorporating this agent in live virus vaccines, made from so-called "normal" embryos. Support for this view has come from the experience of Piedrafita (1951), who observed severe outbreaks of avian leukosis following the use of a formol-killed Newcastle vaccine.

TREATMENT AND CONTROL

In general, no practical therapeutic measures have been found for the avian leukosis complex. Neither the leukemic nor the anemic variety of erythroblastosis responds to iron or liver treatment (Olson, 1936). The unconfirmed results with vitamin-E carriers have been mentioned (Butler and Warren, 1938). Parenteral injections of 10 per cent potassium iodide solution have been suggested for lymphomatosis by Gray (1940). Studies on the chemotherapeutic approach, primarily with folic acid antagonists (Chubb and Laursen, 1954), are of theoretical interest. A field impression that feeding of tomatoes decreases the incidence of lymphomatosis could not be confirmed experimentally by Winton and his associates (1950). It is to

be remembered that temporary remissions of the clinical signs may occur spontaneously.

With the new recognition of the role of the bursa of Fabricius in leukemogenesis, reduction of its influence on the incidence of lymphomatosis has been approached experimentally in two ways: dipping of eggs in testosterone propionate by Glick (1963), and bursectomy before the age of one month by Peterson et al. (1963).

In vaccination attempts for the prevention of the avian leukosis complex, Fritzsche (1938) failed to immunize birds against fowl paralysis with formol-treated tissue vaccine. The presence of the avian leukoses agents in the blood stimulated research on blood sucking parasites as intermediaries. While most of the experiments were negative (Olson, 1940), Johnson (1937) showed the common red mite, *Dermanys-*

sus gallinae, and Brown and Cross (1941) the Texas "blue bug," *Argas persicus,* to be possible mechanical vectors of the lymphomatosis agent. Although not supported by experimental evidence, Carr (1952) re-emphasized the importance of blood-sucking parasites in the transmission of the diseases of the avian leukosis complex. This opinion was recently supported by successful laboratory transmission of Rous sarcoma virus by *Aedes aegypti* and *A. albopictus* (McDaniel *et al.*, 1962). In further studies the same authors (1964) found the virus to survive and perhaps multiply in *Culex pipiens pipiens,* which commonly attacks birds, for at least 16 days. Johnson (1937) also suggested that minor operations, as in fowl pox vaccination, may have the same effect.

On the belief that the egg may be invaded by the lymphomatosis agent both at the time of formation and after commencing its independent existence, Cottral (1949) pointed to the danger of incorporating this agent in live virus vaccines, made from so-called "normal" embryos. Support for this view has come from the experience of Piedrafita (1951), who observed severe outbreaks of avian leukosis following the use of a formol-killed Newcastle vaccine.

TREATMENT AND CONTROL

In general, no practical therapeutic measures have been found for the avian leukosis complex. Neither the leukemic nor the anemic variety of erythroblastosis responds to iron or liver treatment (Olson, 1936). The unconfirmed results with vitamin-E carriers have been mentioned (Butler and Warren, 1938). Parenteral injections of 10 per cent potassium iodide solution have been suggested for lymphomatosis by Gray (1940). Studies on the chemotherapeutic approach, primarily with folic acid antagonists (Chubb and Laursen, 1954), are of theoretical interest. A field impression that feeding of tomatoes decreases the incidence of lymphomatosis could not be confirmed experimentally by Winton and his associates (1950). It is to

In control by breeding, mass selection may be practiced by mating birds surviving to at least the second laying period. Progeny testing will speed up the process of selecting for resistant genes, as is the case with other multifactorial characters.

In control by isolation, a partial application of this principle calls for brooding chicks in clean houses as far away from mature stock as possible. Separate attendance is advisable. The first two weeks are the most critical ones. For best results, complete isolation should be maintained by brooding and rearing the growing stock on a separate farm, not otherwise stocked, for at least five months before bringing it back to the main plant. Under these conditions it is hoped that genetically resistant stock will be enabled to withstand ordinary exposure to the avian leukosis complex.

2. In non-self-sustaining flocks, chicks should be purchased from breeders who have adopted some or all of the above measures. Since, however, no practical

tests are available for the detection of latent carriers of the leukosis complex in the breeding stock, the seller should not be held responsible for losses resulting from it.

Exacting sanitary and quarantine measures are advisable during the entire brooder stage and early maturity to prevent transmission by contact and the possible precipitating effect of secondary parasitic factors.

3. Ectoparasites should be kept in check at all times. Minor operative procedures, such as vaccination, caponizing, debeaking, etc., should be carried out with certain aseptic precautions. Producers of embryo-derived avian vaccines should realize the potential danger from latent egg-borne viruses and exert sanitary control over the source flocks. Eventually the use of chicken embryos from RIF-free flocks will be highly advisable, as is already required for the production of live chicken embryo derived human vaccines.

Electron Microscope Studies of Avian Leukosis Tumors*

Electron microscopy of ultrathin sections of chicken tumors has contributed greatly to our knowledge of the nature of the viruses causing these tumors and to our understanding of virus-cell relationship in the cells of tumors and leukemias of chickens. It has demonstrated the morphology of virus particles and the sites of their replication in the infected cells. Biological, biophysical, biochemical, as well as cytochemical studies combined with electron microscopy have contributed to significant advances in our knowledge of these agents and have led to a quantitative correlation between virus particles and the tumor-inducing properties of the tissues in which they have been observed. Electron microscopy has also helped to demonstrate that many cell types, as in the infectious processes induced by many nontumor viruses, may participate in the response of the susceptible host to an infection with avian tumor viruses.

ROUS SARCOMA

Previous studies on Rous sarcoma tumor cells and Rous sarcoma virus particles have been extensively presented in a number of reviews (Bernhard, 1958, 1960; Dmochowski, 1960a, b; Haguenau, 1960).

Particles suggestive of virus were first observed in Rous sarcoma cells grown in tissue culture (Claude *et al.*, 1947) before the introduction of the ultrathin sectioning technique to electron microscopy. It

took a number of years before virus particles were found in thin sections of this tumor (Gaylord, 1955). Subsequently, numerous studies on Rous tumor cells grown *in vivo* and *in vitro*, as well as on normal cells grown in tissue cultures infected with Rous sarcoma virus, confirmed and extended these early observations (Bernhard *et al.*, 1956; Haguenau *et al.*, 1958, 1960a, b; Haguenau, 1960).

Virus particles (800 Å) have been found at the cell surface and in vacuoles of the cytoplasm of tumor cells (Bernhard *et al.*, 1956) and in fibroblasts infected *in vitro* with Rous sarcoma virus (Haguenau *et al.*, 1960b). As seen in the electron microscope, the relationship of Rous sarcoma virus to the constituents of sarcoma cells may appear in a number of forms seen not only in the tumor cells grown *in vitro* or in the fibroblasts infected with the virus *in vitro* (Beard, 1963) but also in tumor cells grown *in vivo* (Dmochowski *et al.*, 1964).

Several types of cells, such as fibroblasts, macrophagelike cells, and mast cells have been described in the Rous sarcoma tumor (Haguenau and Beard, 1962). Cytoplasmic vacuoles, some containing characteristic virus particles, have been observed in all these cells (Haguenau and Beard, 1962; Dmochowski *et al.*, 1964). This is shown in Figures 19.25 and 19.26. No evidence of a specific relationship with virus particles could be seen in some of the vacuoles. The virus particles may be present in these vacuoles as the result of pinocytosis or phagocytosis, especially in the cells of the macrophage type (Haguenau and Beard,

[589]
FIG. 19.25 — Appearance of a Rous sarcoma cell with virus particles adhering to the plasma membrane and with a cytoplasmic vacuole, containing virus particles (in frame). ×30,000.

1962). Structures have been found in Rous sarcoma cells grown *in vitro* (Haguenau and Beard, 1962) which consist of closely packed typical virus particles in a matrix of amorphous osmiophilic material, and apparently not surrounded by a limiting membrane. In our studies on Rous sarcoma induced by the Bryan strain of virus (Bryan, 1959), structures have been ob-

served in Rous sarcoma cells *in vivo* similar to those described in Rous sarcoma cells *in vitro*. In addition, structures have been found (Dmochowski *et al.*, 1964) identical in appearance to cytoplasmic inclusion bodies (Fig. 19.27) (Dmochowski *et al.*, 1961) or to gray bodies or viroplasts (Beard, 1968) observed in myeloblastosis, erythroblastosis, visceral lymphomatosis,

FIG. 19.26 — Part of Fig. 19.25 (in frame) at higher magnification. ×150,000.

FIG. 19.27 — Part of cytoplasm of Rous sarcoma cell, showing cytoplasmic inclusion, with virus particles, surrounded by a membrane. ×90,000.
and nephroblastoma. What could be described as intermediate structures between those surrounded by a single or a double limiting membrane containing closely packed virus particles in a densely osmiophilie material and those without any evidence of a limiting membrane have also been found in Rous sarcoma cells *in vivo* (Dmochowski *et al.*, 1964). These structures appear to be loci of virus synthesis, and the disappearance of a membrane surrounding these structures may lead to virus

particle dissemination by a process the reverse of pinocytosis. The walled-in cytoplasmic inclusions have also been found to undergo progressive vacuolization like those in chicken leukosis which may be removed by a similar process of reverse pinocytosis.

Structures, similar to "viroplasm" (Beard, 1963), were originally described in the cytoplasm of Rous tumor cells by Bernhard *et al.* (1956). These structures, at first, could not be found in other studies
